Soon after the publication of Prof. P. M. S. Blackett's paper[1], Dr. E. C. Bullard suggested to us that it should be possible to test Blackett's theory against other theories by measurements of the magnetic field of the earth in the mines of the Witwatersrand. By courtesy of the management of the Blyvooruitzicht G.M. Co., we made a series of underground observations on Blyvooruitzicht mine.

Using an Askania horizontal magnetometer (Schmidt type), we measured ΔH at five points underground on three successive days, giving in all fifteen determinations of ΔH. A similar instrument was read at the surface at 5-min. intervals during the duration of the underground measurements, so that we were able to allow for diurnal variation. The observations were not as satisfactory as we had hoped, in that there was a larger closing difference than we had expected when the underground instrument was brought back to the surface base station after the observations underground. This difference amounted to 14, 22 and 32 gamma on the three separate days.

The observations were referred to the mean of the values found at four points on an east–west line of 300 yd. centred above the points at which the underground observations were made. The closing error was allowed for in two ways: (1) it was assumed that it was due to random errors of reading, and ΔH was calculated from the mean of the initial and final surface readings; (2) it was assumed that the closing difference was due to a drift linear in time.

The final results for the full fifteen sets of observations with their standard deviations are:

H (underground) $-$ H (surface) $= -26 \pm 4\gamma$, corrected according to (1), and
H (underground) $-$ H (surface) $= -24 \pm 4\gamma$, corrected according to (2).

For the three days separately, these results were:

-31 ± 9, -21 ± 4 and -25 ± 2, corrected according to (1); and
-30 ± 10, -19 ± 4 and -23 ± 1, corrected according to (2).

The mean depth of the observation points below the mean surface for a distance of five miles from the observation point was 4,800 ft.

In a private communication (to be published), S. K. Runcorn compares the variation of the field with depth for Blackett's theory and for all theories which attribute the magnetism to processes in the central core of the earth. He obtains the formula:

$$\text{Blackett's theory: } H_d = H_0 \left\{1 - 2\left(\frac{5\rho_1}{\rho} + 1\right)\frac{d}{a}\right\};$$

$$\text{Core theories: } H_d = H_0 \left(1 + 3\,\frac{d}{a}\right);$$

where H_0 is H at surface, H_d is H at depth d, a is radius of the earth, ρ_1 is mean density of rocks to depth d, and ρ is mean density of the earth. From these formulæ, for a depth of 4,800 ft., we calculate

$$\Delta H = -26\,\gamma \text{ (Blackett's theory)};$$
$$\Delta H = +11\,\gamma \text{ (Core theory)}.$$

Before comparing the theoretical and observed effects, it is necessary to point out that the lower Witwatersrand system which underlies the underground observation point contains several shale bands which produce considerable anomalies at the surface (Krahmann[2]). Calculations based on Krahmann's values show that the shales produce a relative decrease at depth of not more than 9 γ. In addition, there were two dykes in the neighbourhood of the observation area which can be expected to give a relative decrease of not more than 5 γ. The effect of the local geological structure is thus to produce a decrease of at most 14 γ, and it might be as little as 6 γ. Allowing for the geological effects:

(1) H (underground) $-$ H (surface) $= -12 \pm 4$, or $-20 \pm 4\gamma$;
(2) H (underground) $-$ H (surface) $= -10 \pm 4$, or $-18 \pm 4\gamma$.

Even taking our lower limit, the results differ significantly from the core theory. They also differ significantly from the values calculated on the basis of Runcorn's formula. This difference may be accounted for by the fact that Runcorn's formula applies strictly to depth below the mean surface of the whole earth, whereas the mean surface level at Blyvooruitzicht is 5,200 ft. above mean sea-level. It is also possible that there is some geological factor of which we have not taken account. The uncertainty arising from local geological structure should be eliminated by an extended series of observations together with a detailed surface survey, which it is intended to carry out.

In addition to the management and staff of the Blyvooruitzicht G.M. Co., we are indebted to the director, Geological Survey Office, for the loan of instruments.

Universal Constants in Blackett's Formula

Recently, Blackett[1] has suggested that the formula

$$P = \beta \,.\, \frac{G^{1/2}U}{c}$$

represents a fundamental relation between the angular momentum U and the magnetic moment P of a massive rotating body; where G is the gravitational constant, c the velocity of the light and β a dimensionless constant of the order of unity. If the formula were true, it would be a great aid towards finding a theory unifying the gravitational and the electromagnetic field. It is, therefore, interesting to investigate what conditions the formula would impose upon such a future theory. If we assume that the equations of the new theory can be derived from a Lagrangian, and that the magnetic moment of a rotating body is originated through some cross-terms between the gravitational and the electromagnetic field quantities in the Lagrangian, then it would be found that there must be other universal constants than G and c in the theory.

Generally, the building materials available for forming a Lagrangian in a unified field theory are the various field quantities and the various universal constants. As building operations, there are summation, multiplication, squaring, taking roots, etc. Before commencing each step of summation it must be ensured that the different terms of the sum have the same dimensions. This is the step at which the universal constants enter into the theory. For example, the electromagnetic interaction is generally introduced by replacing the operator $\partial/\partial x^\mu$ by the following sum of operators

$$\frac{\partial}{\partial x^\mu} - \frac{i}{e} A_\mu,$$

where A_μ is the electromagnetic four-potential. In order to make the two terms of the same dimensions, it is necessary to introduce a constant e of the dimensions of charge.

In general, three 'linearly independent' universal constants would enable us to meet any such situation. From three such constants, numerical factors of any dimensions can be formed to ensure the uniqueness of the dimensions of the different terms in a sum. Even in the pioneering attempt of Weyl[2] to unify the gravitational and the electromagnetic field, a constant of the dimensions of charge was implicitly introduced besides G and c. It was introduced when he generalized Christoffel's three index symbols by replacing the operator $\partial/\partial x^\mu$ by the sum

$$\frac{\partial}{\partial x^\mu} + \varphi_\mu,$$

where φ_μ is connected with A_μ through this new constant. It seems that three universal constants would be the minimum number needed in building a unified field theory. If there were only the two constants, G and c, available, the possibilities of building a Lagrangian would be severely limited. Only those combinations of field quantities, the dimensions of which are different from each other by a factor $G^p c^q$, can be used to form a sum where p and q are any rational numbers. On the cross-terms, which are supposed to cause the magnetic moment of a rotating body, the following conditions are then imposed:

(*a*) One condition to ensure that the cross-terms are invariant with respect to co-ordinate transformations. This condition does not depend upon the number of universal constants.

(*b*) Three conditions to ensure that the cross-terms have the dimension cm.$^{-2}$ in the gravitational unit.

(*c*) Three conditions to ensure that the magnetic moment has a dependence on G, c and ρ as given by Blackett's formula, where ρ is the invariant density of the rotating body.

Detailed investigation shows that there exists only a very limited number of cross-terms of different structures which satisfy all the above conditions. Further, none of these cross-terms gives a satisfactory result. If the metric tensor of the gravitational field were not introduced into the cross-terms, the only possible cross-term has the form

$$\frac{G^{3/2}}{c^4} \rho A_\mu u^\mu.$$

u^μ is here the four-velocity of the element of matter. This would give the earth an electrostatic field which is large in comparison with its magnetic field. The metric tensor caused by a rotating body has been given by Lense and Thirring[3] in the first approximation. The non-vanishing, non-diagonal elements have the form

$$\sim \frac{G\,U}{c^3 R^2},$$

where R is the distance from the centre of the rotating body to the point of observation. If this tensor were introduced into the cross-terms, the resulting theory would give a wrong dependence on the angular velocity of the rotating body.

To free the new theory from some of the above conditions, universal constants other than G and c must be introduced. Since such constants must be in Blackett's formula, they must be contained in the factor β. To make β dimensionless, two constants other than G and c are required, unless we are prepared to introduce a constant of the dimension of $G^p c^q$. Generally, the introduction of universal constants is based on physical principles. The principle of the conservation of charge might be used to introduce one constant. However, it is difficult to imagine what is the other principle which can introduce the other constant. It appears, therefore, that some new physical principle lies behind Blackett's formula.

I wish to express my thanks to Prof. L. Rosenfeld for his most valuable advice. I also wish to thank Prof. P. M. S. Blackett for his kind encouragement and Mr. J. Hamilton for stimulating discussions.

Penetration of Magnetic Field into Superconductors

We have repeated Casimir's experiment[1] designed to measure the variation with temperature of the penetration depth (λ) of a magnetic field into a massive superconductor. The principle of the experiment is to measure at various temperatures the mutual inductance of two coils wound on a superconducting core; if the magnetic field of the primary coil penetrates slightly into the superconductor, the flux linkage with the secondary coil, and hence the mutual inductance, is slightly greater than if there were no penetration. A small decrease of mutual inductance should therefore be observed as the temperature, and with it, λ, is reduced.

Our experimental arrangement was very similar to that used by Casimir; 75 cycles/sec. A.C. was used in the bridge, and with a measuring current in the primary which produced a peak magnetic field of 0·5 gauss, it was possible to detect changes as small as 0·01 μH, so that the expected effect of order 0·5 μH could be measured with a few per cent accuracy. In his original experiment Casimir found no appreciable effect for mercury; but, as he has kindly informed us, it is likely that this was because the mutual inductance was mounted on an evacuated quartz tube containing the mercury; as the vapour pressure of the helium bath was lowered to reduce the temperature, the tube would have expanded slightly and thus produced a compensating decrease of mutual inductance. This possibility was avoided in our experiment by leaving the quartz tube open, and the expected increase of mutual inductance was found for both mercury and tin.

Unambiguous results were obtained with a freshly machined tin cylinder and a slowly frozen mercury cylinder, in each case cooled through the transition temperature with the earth's magnetic field compensated. In these circumstances the change of mutual inductance was unaccompanied by any appreciable out-of-phase component. We confirmed Casimir's observation that if the earth's field was uncompensated the change of mutual inductance was greater, but accompanied by a temperature-dependent out-of-phase component; this was probably due to a slight locking-in of flux across the cylinder, which left some resistive patches of normal metal at the surface, of an area inversely proportional to the critical field. We found also that if the tin had been exposed to air for some weeks or was rough, temperature-dependent resistive losses again appeared; and, moreover, the results became sensitive to the strength of the alternating magnetic field of the measuring current.

For tin the variation of $\Delta\lambda = \lambda(T) - \lambda$ (2·1° K.), deduced from the observed change of mutual inductance, with ΔT, the temperature difference from the transition temperature, is shown in Fig. 1. We have plotted also the points obtained by Pippard[2] using a radio-frequency method and by Désirant and Shoenberg (unpublished) from magnetic measurements of tin-filled capillaries; it will be seen that there is fair agreement. For mercury, different results were obtained with two different specimens, but in both cases the values of $\Delta\lambda$ are, within the limits of experimental error, proportional to those obtained by Désirant and Shoenberg[3] from magnetic measurements of bundles of mercury-filled capillaries (Fig. 2). Now Ginsburg[4] has pointed out that the penetration depth could depend on the direction of current-flow relative to the crystal axes, and such anisotropy may well be the cause of the discrepancy. It is, in fact, likely that the two mercury specimens were both single crystals or nearly so, but with different crystal orientations; so that the effective penetration depth would have been different in the two specimens. In the experiments of Désirant and Shoenberg, even if the individual cylinders had been single crystals, the large number of capillaries would have averaged out any directional effects and given a result characteristic of a polycrystal. The agreement between the present results and those of Pippard for tin is also plausible, since in both cases it is probable that the surface was polycrystalline; the slight differences may be due to slightly different preferred orientations. The fact that for mercury it is only the scale of the $\Delta\lambda - \Delta T$ curve which depends on crystal orientation is reasonable, for in terms of the London theory[5] it would mean that the effective mass of the superconducting electrons varied with the current direction in a crystal, but the ratio of masses in different directions did not vary with temperature (we have to thank Dr. H. London for this observation).

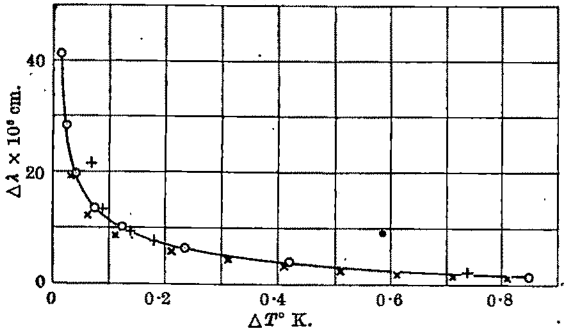

Fig. 1. RESULTS FOR TIN

o—o—o Present results, T_c = 3·711° K.
+ Désirant and Shoenberg, T_c = 3·738° K.
× Pippard, T_c = 3·711° K.

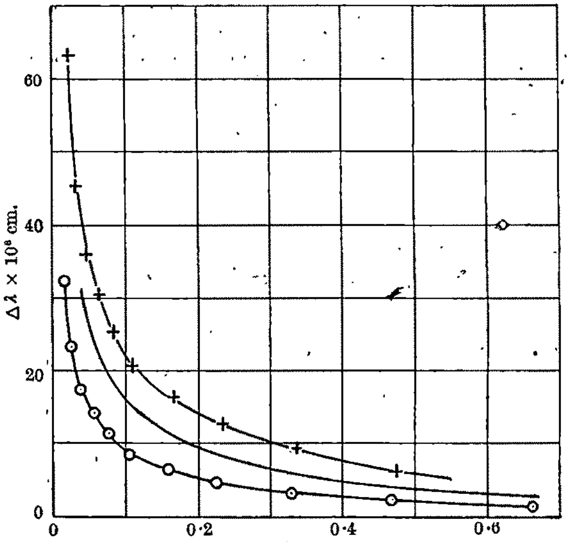

Fig. 2. RESULTS FOR MERCURY

o—o—o Present results (a), T_c = 4·158° K.
———— Désirant and Shoenberg, T_c = 4·17° K.
+—+—+ Present results (b), T_c = 4·165° K.

A few experiments were made to see whether there was any evidence for variation of penetration depth with magnetic field, an effect also predicted by Ginsburg[6]. A steady field was superimposed on the small alternating measuring field, but produced no appreciable effect up to about 0·5 of the critical field. For higher fields an apparent rise of penetration depth was obtained which eventually became very great, but since it was accompanied by a rapidly increasing out-of-phase component in the mutual inductance, it is not possible to obtain any definite interpretation; a genuine increase of penetration depth in this region of an amount comparable to the changes with temperature is certainly not excluded.

The experiments are being continued with the aim of obtaining precise data on the anisotropic effects, and to investigate the field dependence of λ.

Radiations from Uranium (239) and Neptunium (239)

IN a recent communication[1] Slätis has reported on experiments on the β- and γ-radiations from $^{239}_{92}$U and $^{239}_{93}$Np, using magnetic analysis and absorption methods for the two types of radiation respectively.

For $^{239}_{92}$U the nuclear γ-radiation of 76 ± 3 keV. energy, first reported by Feather and Krishnan[2], has been confirmed, and its energy fixed as 73·2 ± 0·3 keV. by measurements on the line spectrum of L- and M-photo-electrons. Also, there is satisfactory agreement between the new value for the energy-limit of the main β-spectrum (1·12 MeV.) and the value (1·20 ± 0·02 MeV.) deduced from the absorption curve. But a serious discrepancy is evident between the conclusions indicated by the level scheme of Fig. 2 of Slätis's paper and the earlier results. The level scheme in question indicates that a γ-radiation of energy 870 keV. is emitted in cascade with the 73 keV. transition. Now it would appear that the only evidence for the assumption that a quantum of 870 keV. radiation is emitted in nearly every disintegration (as distinct from occasionally) is in the results of the analysis of the continuous β-spectrum by the Fermi method. This analysis is reported to yield a second high-energy component of feeble intensity and limiting energy 2·06 MeV. No such component was detected by the absorption method (it would have been a simple matter to have detected a high-energy component of intensity 0·05 in this way); furthermore, the published results of Feather and Krishnan set an upper limit of about the same magnitude (0·05) to the emission probability of a possible 870 keV. quantum.

We also observed a second γ-radiation, and estimated its intensity at about 0·10 per disintegration on the assumption that the quantum energy was of the order of 300–600 keV. If the energy were assumed to be twice as great, the calculated intensity would be roughly halved. It would seem, therefore, that the level scheme of Slätis's Fig. 2 cannot be substantiated, and that the total disintegration energy of $^{239}_{92}$U is 1·20 ± 0 05 MeV., not 2·06 MeV. The β-spectrum which was observed to have the latter energy limit must, in this case, have another origin.

As regards $^{239}_{93}$Np, it is interesting to compare the results of the Fermi analysis of Slätis with unpublished results which I obtained by the absorption method early in 1941[3]. Analysing the complete absorption curve of the β- and γ-radiation by standard methods[4], it was then concluded that the β-radiation of $^{239}_{93}$Np was constituted as follows:

	Energy (keV.)	Intensity
Photo-electrons	—	~ 0·6
Partial spectrum 1	140 ± 25	~ 0·2
" " 2	400 ± 20	0·7
" " 3	630 ± 20	0·1
" " 4	> 1000	< 0·05

Slätis's analysis leads to maximum energies of 288, 403, 676 and 1,179 keV., and, as concerns intensities, the preliminary report merely indicates that the second partial spectrum with end-point at 403 keV. is the most intense.

The general similarity of the results is not without significance, particularly in relation to the claim that, under suitable control, the absorption method can be of real use in the analysis of complex β-spectra, so long as sufficiently detailed observations are made. It might be mentioned in this connexion that the absorption measurements on the β-radiation of $^{239}_{93}$Np were made using sources of less than 10^{-4} mC. strength obtained from the decay of $^{239}_{92}$U produced by the (d, p) reaction with uranium on the Cambridge cyclotron. Chemical separations were made under the direction of Dr. E. Bretscher, to whom belated thanks are now recorded.

Autoradiograph Technique

EXPERIMENTS aiming at an improvement of the resolution obtained with the autoradiograph technique were recently carried out, and a short outline of the methods used is given here.

15 μC. of radioactive iodine (I^{131}) were injected subcutaneously into a rat (wt. 125 gm.). The thyroid was fixed in alcohol and sections 5 μ thick were cut after embedding in paraffin. Fig. 1 shows a photomicrograph of a stained section of the thyroid. After dissolving the paraffin, sections were brought into contact with the photographic film or plate, and the two pressed together in a printing frame and left there for a suitable time of exposure. The sections were not coated with 'Colloidin' before exposure. The film or plate was then developed and fixed[1,2]. Of the various emulsions tried, Ilford Line film showed the best resolution. Fig. 2 shows an autoradiograph made from the section shown in Fig. 1 before staining, the well-known fact that iodine is concentrated in the colloid of the thyroid follicles appearing clearly in the autoradiograph. Colloid particles 10 μ apart can still be distinguished as separate units; if the distance is 15 μ the separation is very clear. The exposure is about twenty times that needed for a fast X-ray film.

In order to improve resolution, stripping emulsion was removed from its base and immersed in water. A slide carrying a section was placed underneath the emulsion, both lifted out of the water and dried quickly in front of a fan. The slides were then left

Fig. 1

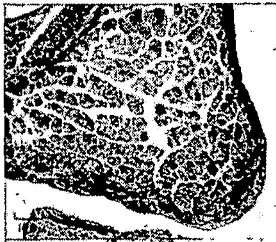

Fig. 2

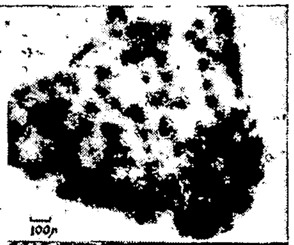

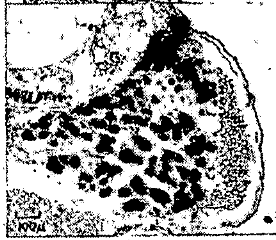

Fig. 3

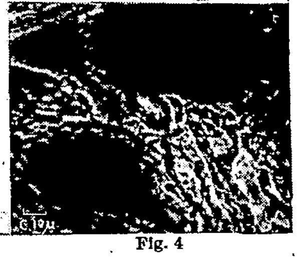

Fig. 4

in a light-proof container and developed and fixed after a suitable interval. The original section and the autoradiograph are superimposed and can be viewed simultaneously. Fig. 3 shows a photomicrograph, and the improved resolution can be judged by comparison with Fig. 2. Determination of the location of the radioactive substance will be facilitated as both cells and autoradiograph can be viewed simultaneously. Methods of staining through the covering layer of gelatine were tried but have so far been unsuccessful. A photomicrograph taken with the phase-contrast microscope (Fig. 4) depicts the ring of cells around the colloid with sufficient detail for judging the location of the radioactive material. The resolution of the autoradiograph can also be judged from this illustration.

Ilford half-tone, thin film, dry stripping emulsion was found very suitable. The exposure is about four times that needed for a fast X-ray film. Specially prepared slides which prevent lifting off of the emulsion during processing were supplied by Kodak, Ltd.

I wish to thank Dr. I. Doniach, of the British Postgraduate Medical School, for the histological work done; Dr. A. F. W. Hughes, of the Strangeways Laboratory, Cambridge, for preparing the photomicrograph Fig. 4; and Mr. C. Waller, of Messrs. Ilford, Ltd., and Dr. R. H. Herz, of Messrs. Kodak, Ltd., for much helpful discussion.

Entropy Fluctuations in Liquid Helium II and the Rayleigh Line

It is known[1] that in the scattered light spectra of liquids the Rayleigh line exhibits an undisplaced component of the same frequency as the exciting light and two displaced components on either side of the undisplaced line. It was shown by Landau and Placzek[2] that the intensity I_u of the undisplaced component and the sum of the intensities $2I_v$ of the displaced components is given by

$$\frac{I_u}{2I_v} = \frac{C_p - C_v}{C_v},$$

where C_p and C_v are the specific heats at constant pressure and constant volume respectively. The Landau – Placzek relation accords with experiment reasonably well for several liquids. Recently, Gross[3] has given an interesting derivation of the Landau–Placzek relation. He has shown that the undisplaced component is caused by entropy fluctuations, and the displaced components arise on account of the density fluctuations. The density fluctuations, constituting as they do the Debye elastic-vibrations, travel in a liquid with the velocity of the Debye-waves. The entropy fluctuations, on the other hand, can be regarded as stationary, and hence give rise to the undisplaced component.

The present note is concerned with an application of the theory of Landau and Placzek, and Gross, to liquid helium II. As has been shown by Landau[4] in liquid helium II we have to deal with two velocities of sound waves, a result which has been confirmed by the experiments of Peshkov[5]. One wave is the normal one, that is, due to density fluctuations, and the second sound wave is due to entropy fluctuations. In liquid helium II, the entropy fluctuations are no longer stationary but travel with a velocity which is zero at the λ-point, increases with increasing temperature (T) and approaches the value $C_1/\sqrt{3}$ as $T \rightarrow 0$, where C_1 is the velocity of the density waves (normal sound). It therefore follows that the Rayleigh line in liquid helium II should show a structure radically different from that in other liquids. Instead of the undisplaced component and the two displaced components there should arise (as $T \rightarrow 0$) four displaced components and no undisplaced component. The experimental observation of the scattering of liquid helium II, if accomplished, will throw an interesting light on the existence of normal and super-fluid liquid in helium II.

Third-Order Elastic Coefficients of Crystals

It is well known that the number of independent second-order elastic coefficients required to describe the behaviour of cubic crystals is three, irrespective of the class to which they belong, whereas the corresponding number for isotropic bodies is two. That a crystal of the cubic system differs from an isotropic body in another important respect, namely, its photo-elastic behaviour, was discovered by Pockels. Pockels, however, as in the case of elasticity, made no distinction between the five classes of crystals coming under the cubic system, but assigned three coefficients only for all of them. Contrary to this, one of us[1] showed, by a different method based on group theory, that the T and T_h classes of the cubic system require four coefficients for the description of their photo-elastic behaviour, whereas the other three classes T_d, O and O_h require only three. This prediction has been verified by us experimentally by working with crystals of potassium alum[2].

Recent work of Francis Birch[3] on the theory of finite strain is of interest in this connexion because he has reported that the number of third-order coefficients required to describe the behaviour of cubic crystals is eight for the T, T_h and T_d classes and six for the O and O_h classes. Birch has shown that the maximum number of such coefficients permissible in a triclinic crystal is 56. The method developed by us is of such wide applicability that the numbers of coefficients required to describe any physical property can be easily calculated for all the crystal classes, and this has been done in papers published elsewhere[4].

We have now extended this method to the case of finite strain. The notation used is the same as that adopted in our earlier papers. The character of the matrix relating to the transformation of the 56 coefficients under a general symmetry operation consisting either of a rotation through φ or of a rotation through φ accompanied by a reflexion works out to be

$64\cos^6\varphi \pm 32\cos^5\varphi - 48\cos^4\varphi \mp 8\cos^3\varphi + 16\cos^2\varphi$. Where alternatives occur, the upper or the lower sign should be used respectively for rotation and a rotation reflexion. Using this character and the general formula derived in the earlier papers, the numbers of coefficients for each class are obtained as 56 for C_1 and C_i; 32 for C_s, C_2 and C_{2h}; 20 for C_{2v}, D_2 and D_{2h}; 16 for C_4, S_4 and C_{4h}; 12 for C_{4v}, D_{2d}, D_4 and D_{4h}; 20 for C_3 and S_6; 14 for C_{3v}, D_3 and D_{3d}; 12 for C_{3h}, C_6 and C_{6h}; 10 for D_{3h}, C_{6v}, D_6 and D_{6h}; 8 for T and T_h; 6 for T_d, O and O_h.

These results show that there is a distinction, as in the case of photo-elasticity, between the T and T_h classes of the cubic system on one hand and the T_d, O and O_h classes on the other. They confirm the findings of Francis Birch in all respects except in the T_d class, for which he states that eight coefficients are required. This is presumably due to his not having taken into account a four-fold rotation reflexion axis which this class possesses.

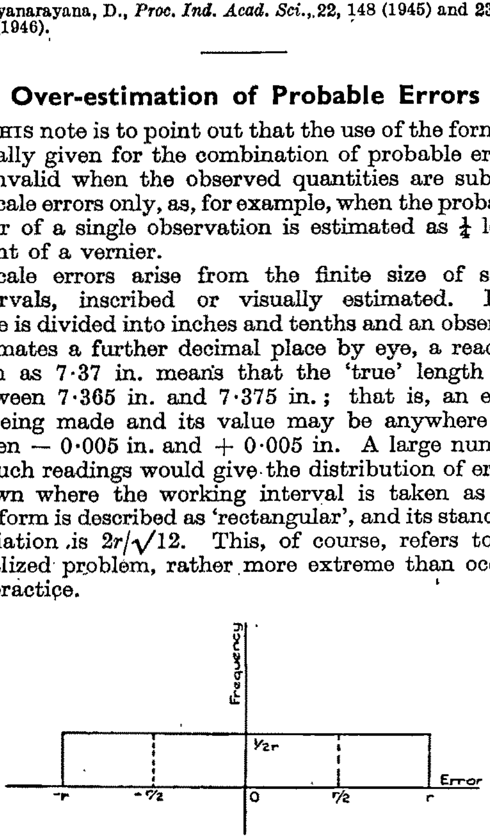
Over-estimation of Probable Errors

This note is to point out that the use of the formula usually given for the combination of probable errors is invalid when the observed quantities are subject to scale errors only, as, for example, when the probable error of a single observation is estimated as ¼ least count of a vernier.

Scale errors arise from the finite size of scale intervals, inscribed or visually estimated. If a scale is divided into inches and tenths and an observer estimates a further decimal place by eye, a reading such as 7·37 in. means that the 'true' length lies between 7·365 in. and 7·375 in.; that is, an error is being made and its value may be anywhere between − 0·005 in. and + 0·005 in. A large number of such readings would give the distribution of errors shown where the working interval is taken as $2r$; the form is described as 'rectangular', and its standard deviation is $2r/\sqrt{12}$. This, of course, refers to an idealized problem, rather more extreme than occurs in practice.



The 'probable error' is defined as the value of the deviation beyond which half the observations lie; in the case of the rectangular distribution it is $r/2$; the probable error of a reading of a vernier scale with least count 0·01 in. is 0·0025 in. (On the other hand, if repeated observations of a quantity give a standard deviation of σ, and the errors are assumed normally distributed, the probable error of a single observation is $0{\cdot}6745\sigma$.)

Let z be a linear function of $u, v, w \ldots$, say, $z = au + bv + cw + \ldots$, then the error in z due to errors in $u, v, w, \ldots$ is

$$p^2 = a^2p_1^2 + b^2p_2^2 + \ldots, \tag{1}$$

where p is probable error of z, p_1 that of u, p_2 that of v, etc. This rule is valid for normal distribution of errors in $u, v, w, \ldots$; but errors following a rectangular distribution cannot be combined in this way because the error of a linear function of a number of such variables has not itself a rectangular distribution. Hence its probable error forms a different fraction of the range, or more correctly, of the standard deviation. The difficulty arises because the probable error depends on the form of the distribution, and no simple method exists for combining probable errors of different types of distribution. It is quite different with the standard deviation, which measures the dispersion of the distribution, and combines by a simple rule for very general forms of the component distributions[1]. Thus, if $\sigma, \sigma_1, \sigma_2, \ldots$ are standard deviations of $z, u, v, \ldots$ respectively, then

$$\sigma^2 = a^2\sigma_1^2 + b^2\sigma_2^2 + c^2\sigma_3^2 + \ldots \tag{2}$$

This equation readily yields (1) when errors in $u, v, w, \ldots$ are distributed normally. On the contrary, if errors in $u, v, w, \ldots$ are scale errors only, estimated from working intervals $2r_1, 2r_2, 2r_3, \ldots$, the respective standard deviations are $2r_1/\sqrt{12}$, $2r_2/\sqrt{12}$, $2r_3/\sqrt{12}, \ldots$ and (2) gives

$$\sigma^2 = \tfrac{1}{3}(a^2r_1^2 + b^2r_2^2 + c^2r_3^2 + \ldots). \tag{3}$$

It is known that the distribution of the sum of a number of rectangularly distributed variables tends to normality[2] fairly rapidly as the number increases, so that σ will be the standard deviation of a nearly normal distribution, in which case $p \doteqdot 0{\cdot}6745\sigma$. Applied in the same problem, (1) would have yielded

$$\begin{aligned} p^2 &= a^2(\tfrac{1}{2}r_1)^2 + b^2(\tfrac{1}{2}r_2)^2 + c^2(\tfrac{1}{2}r_3)^2 + \ldots \\ &= \tfrac{3}{4}\sigma^2, \text{ or } p = 0{\cdot}8660\sigma. \end{aligned} \tag{4}$$

This represents an over-estimation by 28 per cent on the value obtained from (3), but, as will be shown below, the latter is itself slightly in defect.

The only treatment of errors of interval to my knowledge is that given by Gibbs[3], where approximations are obtained for the probable error of z with $a, b, c, \ldots$ restricted to the values + 1 and $2r_1 = 2r_2 = 2r_3 = \ldots 1$; the method over-estimates p. An exact treatment may be based on the cumulated probability function for the sum of n rectangular variables

$$\frac{1}{n!}\sum_{x \geqslant j}(-1)^j\binom{n}{j}(x-j)^n. \tag{5}$$

It is of interest to compare the approximations based on (3), and the fallacious values obtained from (1), with the exact probable errors based on (5) (probable errors given in terms of interval).

No. of variables (n) =	1	2	3	4	5	6	7
Method of estimation of probable error:							
Exact (5)	0·250	0·293	0·353	0·403	0·447	0·487	0·525
Normal (3)	0·195	0·276	0·337	0·390	0·435	0·477	0·515
Fallacious (1)	0·250	0·353	0·433	0·500	0·559	0·612	0·661
Under-estimation by (3), per cent	22·0	6·2	4·7	3·2	2·8	2·1	1·9
Over-estimation by (1), per cent	0	20·5	22·7	24·1	25·1	25·7	25·9

When more than three errors are combined by method (3), the departure from the correct estimate is so slight that it can be ignored; but the over-estimation by formula (1) is serious in all cases.

The essential point is this. If the probable error of a variable directly measured is calculated from the standard deviation of repeated measurements (assumed normally distributed), equation (1) may be used to calculate the probable error of a linear function of such variables. On the other hand, if the direct measurements are not repeated but have their probable errors estimated from the working intervals, equation (1) will over-estimate the probable error of the calculated result.

When the magnitude of the scale error differs among the variables, formula (5) must be modified, and the resultant probable error depends on the relative magnitudes of the scale errors. The net result is that equation (3) will not be far out when the scale errors are of about the same magnitude; but when they differ widely, the largest dominates the precision of the result and the rest may be ignored.

It should be noted again that these difficulties arise only when experimenters use 'probable' errors, now generally discarded in applied statistics. It will be a welcome reform in the 'exact' sciences when standard deviations and standard errors are accepted as conventional.

Relationship Between the Dissociation Constants of Unsymmetrical Dicarboxylic Acids

The correlation of the first and second dissociation constants of symmetrical dicarboxylic acids with the distance apart of the ionizing groups is well known. An experimentally convenient correlation has not previously been proposed for unsymmetrical acids. For symmetrical acids the relationship may be represented by the equation

$$\log_{10} \frac{K_a'}{\delta\, K_a''} = \frac{N_0\, \varepsilon^2}{2{\cdot}303\, RTD_E r},$$

where K_a' and K_a'' are respectively the first and second measured thermodynamic dissociation constants, δ is a symmetry number (in this case 4), N_0 the Avogadro number, ε the electronic charge, R the gas constant, T the absolute temperature and D_E the effective dielectric constant for the space between the two ionizing groups separated by the distance r. For unsymmetrical acids a solution of the problem may be obtained by the following considerations.

In the case of any unsymmetrical dicarboxylic acid HA_1A_2H we write

$$K_a^{\mathrm{I}} = \frac{a_{\mathrm{H}^+} \cdot [\mathrm{H}A_1A_2^-] \cdot f_-}{[\mathrm{H}A_1A_2\mathrm{H}] \cdot f_0} \text{ and } K_a^{\mathrm{II}} = \frac{a_{\mathrm{H}^+} \cdot [A_1A_2\mathrm{H}^-] \cdot f_-}{[\mathrm{H}A_1A_2\mathrm{H}] \cdot f_0}$$

for the thermodynamic dissociation constants corresponding to the two alternative steps for the first dissociation; and

$$K_a^{\mathrm{III}} = \frac{a_{\mathrm{H}^+} \cdot [A_1A_2^{=}] \cdot f_{=}}{[\mathrm{H}A_1A_2^-] \cdot f_-} \text{ and } K_a^{\mathrm{IV}} = \frac{a_{\mathrm{H}^+} \cdot [A_1A_2^{=}] \cdot f_{=}}{[A_1A_2\mathrm{H}^-] \cdot f_-}$$

for the corresponding two alternative routes for the second dissociation. In these expressions f_0, f_- and $f_=$ are the appropriate activity coefficients for the undissociated acid, for the monovalent anions and for the divalent anion respectively.

Now if the unsymmetrical acid be subjected to potentiometric titration we have, for the addition of B equivalents of strong base,

$$A = \text{molarity of the acid} = [\mathrm{H}A_1A_2\mathrm{H}] + [\mathrm{H}A_1A_2^-] + [A_1A_2\mathrm{H}^-] + [A_1A_2^{=}] \text{ and}$$
$$B + [\mathrm{H}^+] = [\mathrm{H}A_1A_2^-] + [A_1A_2\mathrm{H}^-] + 2[A_1A_2^{=}] + [\mathrm{OH}^-].$$

If we then define

$$\alpha = B + [\mathrm{H}^+] - [\mathrm{OH}^-] = [\mathrm{H}A_1A_2^-] + [A_1A_2\mathrm{H}^-] + 2[A_1A_2^{=}]$$
$$\beta = A - B - [\mathrm{H}^+] + [\mathrm{OH}^-] = [\mathrm{H}A_1A_2\mathrm{H}] - [A_1A_2^{=}]$$
$$\text{and } \gamma = 2A - B - [\mathrm{H}^+] + [\mathrm{OH}^-] = 2[\mathrm{H}A_1A_2\mathrm{H}] + [\mathrm{H}A_1A_2^-] + [A_1A_2\mathrm{H}^-]$$

it is readily shown that

$$a_{\mathrm{H}^+}^2 \cdot \left(\frac{\alpha}{\gamma}\right) \cdot \frac{f_=}{f_0} = (K_a^{\mathrm{I}} + K_a^{\mathrm{II}}) \cdot a_{\mathrm{H}^+} \cdot \left(\frac{\beta}{\gamma}\right) \cdot \frac{f_=}{f_-} + \frac{(K_a^{\mathrm{I}} + K_a^{\mathrm{II}})\,(K_a^{\mathrm{III}} \cdot K_a^{\mathrm{IV}})}{(K_a^{\mathrm{III}} + K_a^{\mathrm{IV}})}$$

The constant term in this equation may be simplified by the considerations that

$$K_a^{\mathrm{I}}/K_a^{\mathrm{IV}} = \exp N_0\varepsilon^2/RTD_E r \text{ and } K_a^{\mathrm{II}}/K_a^{\mathrm{III}} = \exp N_0\varepsilon^2/RTD_E r,$$

where the symbols have the significance previously employed. The equation then reduces to

$$a_{\mathrm{H}^+}^2 \cdot \left(\frac{\alpha}{\gamma}\right) \cdot \frac{f_=}{f_0} = (K_a^{\mathrm{I}} + K_a^{\mathrm{II}}) \cdot a_{\mathrm{H}^+} \cdot \left(\frac{\beta}{\gamma}\right) \cdot \frac{f_=}{f_-} + K_a^{\mathrm{I}}K_a^{\mathrm{II}} \cdot \exp - N_0\varepsilon^2/RTD_E r.$$

Clearly this may be plotted as a linear equation, and if either K_a^{I} or K_a^{II} be known, then the electrostatic term $\exp - N_0\varepsilon^2/RTD_E r$ may be evaluated and used for calculation of r. For this purpose it is only necessary to determine the dissociation constant of one of the mono-methyl esters, say, of the acid.

If $K_a^{\mathrm{I}} = K_a^{\mathrm{II}}$ and $K_a^{\mathrm{III}} = K_a^{\mathrm{IV}}$, that is, if the acid be symmetrical, it is readily shown that the equation reduces to a form which has been successfully employed by Speakman[1] for symmetrical dicarboxylic acids.

Application of the equation for unsymmetrical acids to problems in molecular structure will be reported elsewhere.

I thank Prof. H. V. A. Briscoe for his interest in these derivations.

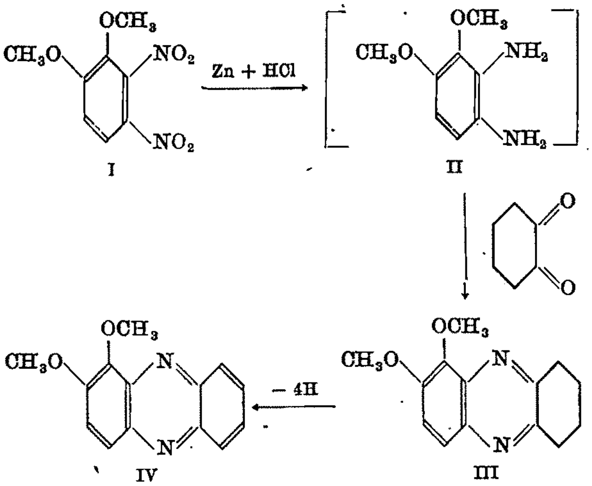
Phenazine Synthesis

Continuing the researches of Clemo and McIlwain[1] on the structure of the pigment of *Chromobacterium iodinum*, we are engaged in the synthesis of phenazines. In view of the recent communication of Slack and Slack[2], describing the preparation of 1 : 2-dimethoxyphenazine, we wish to put on record an independent synthesis using the method of Clemo and McIlwain[3].



An alcoholic solution of 3 : 4-dinitroveratrole[4] (I) was reduced by the action of zinc and hydrochloric acid, and the final solution of the reduction product was condensed with cyclohexane-1 : 2-dione[5], without attempting to isolate the pure free base (II). The resulting 1 : 2-dimethoxy-5 : 6 : 7 : 8-tetrahydrophenazine (III) crystallized from light petroleum (b.p. 40–60°) in straw-coloured needles, m.p. 82–83° (found : C, 69·0 ; H, 6·6. $C_{14}H_{16}O_2N_2$ requires C, 68·9 ; H, 6·6 per cent).

Dehydrogenation of (III) in *p*-cymene solution using palladium charcoal gave 1 : 2-dimethoxyphenazine[2] (IV), which crystallized from light petroleum, b.p. 80–100°, in orange-yellow blades, m.p. 138–139° (found: C, 70·0 ; H, 5·4. $C_{14}H_{12}O_2N_2$ requires C, 70·0 ; H, 5·0 per cent).

Attempts to prove the structure of the bacterial pigment by synthesis are in progress and a full account will be published elsewhere.

Thermal Decomposition of Organic Nitrates

The kinetics and mechanism of the thermal decomposition of organic mono- and poly-nitrates have been studied during recent years by Bawn and Wiseman[1], A. J. B. Robertson[2] and more extensively by me[3]. Studies on the overall decomposition in liquid and vapour phases suggest strongly that fission of O—N bonds with formation of NO_2 is the primary process, while I have shown[3] that during the very early stages of decomposition of a wide range of organic nitrates, in which the occurrence of secondary reactions is prevented, nitrogen is eliminated from the molecule wholly as NO_2. These observations and the identification of aldehydes among the decomposition products indicate that, as suggested earlier by Bawn[1], the mechanism postulated by Appin *et al.*[4] for methyl nitrate applies to organic nitrates in general, namely :

$$RCH_2O - NO_2 \rightarrow RCH_2O^- + NO_2$$
$$RCH_2O^- \rightarrow \tfrac{1}{2}RCHO + \tfrac{1}{2}RCH_2OH,$$

followed by oxidation-reduction reactions between the products.

The pressure/time curves for the overall decomposition of a wide range of these nitrates conform to the first-order relationship over their greater part, but temperature-independent factors are usually abnormally high, ranging from $10^{14 \cdot 7}$ for *n*-propyl nitrate to $10^{20 \cdot 6}$ for mannitol hexanitrate, while apparent activation energies range from 34 to 47 kilo-cal./mole. The magnitude of these temperature-independent factors has aroused considerable speculation, particularly as to the possible incidence of chain reactions, but no satisfactory explanation has been found. Thus Roginski and Sapozhinkoff[5] showed that the rates of decomposition of nitroglycerine in the liquid state and in dilute solution were the same, and also that the usual chain-breakers are without effect ; I find[3] no large difference between decomposition-rates of other polynitrates in the vapour and liquid phases.

The placing of theoretical interpretations on such kinetic constants should, however, be approached with caution, since more than one reaction occurs during decomposition, particularly with polynitrates, the apparent order of reaction being controlled by the fission of O—N bonds, which is a first-order process.

It is improbable, however, that such considerations will account wholly for the abnormally high B factors. This is confirmed by my work on the very early stages of the decomposition of a range of organic nitrates, where secondary reactions are prevented[3]. Here the extent of the decomposition of polynitrates studied is so small that it is reasonable to assume that fission of only one O—N bond is involved. Typical results are shown in the accompanying table.

Nitrate	Temp. (°C.)	k
Ethylene glycol dinitrate	85–105	$10^{15 \cdot 9} \exp - 39000/RT$ sec.$^{-1}$
Trimethylene glycol dinitrate	85–110	$10^{15 \cdot 8} \exp - 38100/RT$ sec.$^{-1}$
Propylene glycol dinitrate	80–100	$10^{15 \cdot 2} \exp - 37400/RT$ sec.$^{-1}$
Nitroglycerine	75–105	$10^{17 \cdot 1} \exp - 40300/RT$ sec.$^{-1}$
Trimethylol-nitromethane trinitrate	75–95	$10^{15 \cdot 9} \exp - 36400/RT$ sec.$^{-1}$

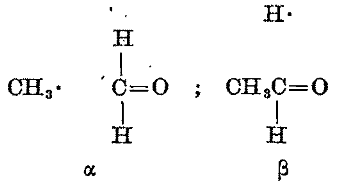
In general, temperature-independent factors are still higher than those normally associated with first-order reactions. The most probable explanation of this, since evidence so far does not support the postulation of long chains, is that appreciable positive entropies of activation due to restricted rotation about C—C bonds are associated with these reactions. Thus on the basis of the activated-complex theory[6], the 'temperature-independent' factor in the Arrhenius equation for a rapid first-order reaction is identified with the expression

$$e \cdot \frac{kT}{h} \cdot \exp \Delta S^{\ddagger}/R,$$

where $\Delta S^{\ddagger}$ is the entropy of activation. Construction of models of polynitrate molecules shows that in the position of closest approach, mutual dipolar repulsion of nitrate groups is probably large enough to set up an appreciable potential barrier to free rotation about

C—C bonds in the initial state. This view is to some extent supported by the results of de Kreux[7] on the dipole moments of organic nitrates. Such a barrier between two nitrate groups should largely disappear in the transition state when one O—N bond is broken, thereby resulting in an appreciable positive entropy of activation.

In the present work it has been shown that the order of stabilities of O—N bonds in the alkyl nitrates is methyl > ethyl > *n*-propyl. This can be explained on the basis of reduction of the O—N bond-energy by the extra resonance-energy of the RCH$_2$O— radical due to a hyperconjugation effect similar to that postulated by Polanyi and Butler[8] for the alkyl halides. Thus the CH_3CH_2O— radical has the extra resonance forms



$$\underset{\alpha}{CH_3\cdot \quad \overset{H}{\underset{H}{|}}\!\!C{=}O} \; ; \; \underset{\beta}{\overset{H\cdot}{}CH_3\underset{H}{C}{=}O} \quad \text{(twice)},$$

the α-form being more probable than the three extra resonance forms in the corresponding CH_3O— radical because of the difference between the C—C and C—H bond energies. Further structural effects observed by me, for example, the de-stabilizing effect of a second nitrate group and of electro-negative groups, can similarly be explained.

Details of this work, which was carried out during 1941–45, will be published elsewhere together with results of more work now in progress in this field.

Reduction of Aniline in Ammonia

IN a recent paper by Watt, Knowles and Morgan[1] on the course of reduction in liquid ammonia the following statement is made: "In view of the results reported by Wooster[2] it is surprising that reduction of nitrobenzene by the sodium-methanol combination yielded aniline and not dihydroaniline—". Unpublished work by me has shown that aniline is reduced by sodium and methanol in liquid ammonia, as would be expected by analogy with the reduction of dimethylaniline[3], which Watt, Knowles and Morgan do not mention. If the reduction is carried out rapidly, the product is a dihydroaniline, probably the 2 : 5-, since acid hydrolysis leads to *cyclo*hexenone. Slow reduction, however, gives chiefly a tetrahydroaniline, probably the 1 : 2 : 5 : 6- ; 3 : 5-dinitrobenzoyl derivative, m.p. 198° (found: C, 53·3; H, 4·6. $C_{13}H_{13}O_6N_3$ requires C, 53·6; H, 4·5 per cent). Its melting point is depressed by admixture with the derivative from aniline, m.p. 235°, and it cannot be an enamine since it is stable to mineral acid. There is little reduction of dimethylaniline past the dihydro-stage under the conditions used here, namely, excess of alcohol, so that the further reduction of dihydroaniline is probably due to isomerization of the enamine to the imine:

$$—CH{=}C(NH_2)— \rightarrow —CH_2C({=}NH)— ;$$

and reduction of the imino-group, rather than to conjugation of the nuclear bonds and reduction of the conjugated system. The latter reaction should lead in any event to an enamine, which would give on acid hydrolysis *cyclo*hexanone, as is, in fact, the case with dimethylaniline in the presence of excess sodium[3]. The facile rearrangement of enamines to imines probably explains the formation of, for example, tetrahydroquinoline rather than dihydroquinoline by reduction of quinoline with sodium and alcohol.

White-eyed Mutants of Diptera

Two recent papers[1,2], as well as an older one[3], compare white-eyed mutants found in *Culex*, *Calliphora* and *Phormica*, respectively, with the white-eyed types long known in *Drosophila*. Since in no *Drosophila* species is more than one single-gene difference known that will give rise to a white eye, it is concluded that these types in other Diptera represent mutations corresponding to the white of *Drosophila*.

There is a special reason why this conclusion cannot be accepted. It has been known for some time that there are two distinct pigments, a red and a brown, in the eye of the wild-type *Drosophila*. The red pigment is absent in the brown mutant; the brown is absent in the vermilion, cinnabar and scarlet mutants; both are absent in white. The results of Becker[4] show that the red pigment is absent in *Calliphora*—in which, therefore, the wild type is like the brown mutant of *Drosophila*. This appears to be the usual condition in insects; the red pigment is apparently present in all Drosophilidæ that I have examined, but seems to be present in only a few of the related families. It should, therefore, not be possible to distinguish the white, vermilion, cinnabar and scarlet mutants in more remote families unless special methods are used.

There is available a method for further differentiation here, namely, the study of the hormones involved in eye-pigment production. As is well known, the white and scarlet mutant types of *Drosophila* are not affected by hormones; but there are two separate hormones involved in the production of the brown pigment, of which vermilion lacks one, cinnabar the other[5]. It has been shown that these hormones are not species-specific in their activity, and cross-tests with *Drosophila* have been made with mutant eye-colours in other insects. In this way it has been shown that the mutant 'ivory' (and its allele 'orange') in the hymenopteron *Habrobracon* is due to a deficiency in the hormone that is lacking in cinnabar *Drosophila*[6], and that there is a similar correspondence in two mutant types of Lepidoptera: the 'red' of *Ephestia* corresponds to vermilion[7], and the 'white-1' of *Bombyx* corresponds to cinnabar[8].

It will be noted that one of these types is in fact white, while another one is only slightly pigmented—as might be expected if a single eye-pigment is present.

Excessive Hydration in an Animal with an Open Type of Circulation

A CONDITION of excessive hydration, with great distension of the body, has been observed in the aquatic crustacean *Asellus*, and is interesting since (1) the relatively rigid crustacean exoskeleton might have been expected to preclude such a condition, and (2) in the open type of circulation, of Crustacea, there is no barrier corresponding to the capillary wall which, in an animal with closed circulation, plays an important part in the etiology of the œdematous type of excess hydration, that is, distension of the tissue spaces with fluid[1].

The condition in *Asellus* has been observed very occasionally in Nature, not infrequently in laboratory stocks, and in 30 per cent of individuals undergoing regeneration of limbs in unfavourable external media. A similar condition develops, particularly in young individuals, during histological fixation. It has been induced experimentally by sealing the surface of the gills (respiratory pleopods) with 'Celloidin'.

The incipient condition affects the gills only, their exoskeleton being particularly thin and pliable. Later, the whole body is affected, distension occurring by the normally flattened body and gills becoming increasingly circular in cross-section and by elongation of the body through the straightening out of the normally infolded intersegmental membranes. The latter process is most marked along the dorsal surface so that the body becomes flexed ventralwards, rigidly, and the limbs of the mid-thoracic segments do not touch the substratum. Muscular movements, depending on normal intersegmental mobility, eventually become impossible. There is probably no stretching of the material of the exoskeleton. Excessively hydrated animals experience difficulty in ecdysis, the condition preventing the necessary contraction of the body[2].

Individuals survive for periods up to sixteen days after the development of visible distension. The amplitude, rate and rhythm of the heart remain apparently normal until the final stages when there is slowing, decreased amplitude, irregular rhythm and asynchrony between the two ends of the elongated organ.

The condition is relieved immediately throughout the body by permitting hæmorrhage, either by piercing the body-wall or by removing a limb. There is an apparent return to complete normality and the distension is clearly hydræmic and not œdemic in nature. The body-wall is not passively distended, but develops considerable tension. Normal muscular movements are restored immediately by deflation. The relief is temporary (1–3 hours).

The distension may be reduced by hypertonic concentrations of such solutes as sodium chloride, sugar and gum arabic in the external medium, the large molecules being the most effective in equimolar concentrations. Relief persists for 12–24 hours. Moderate desiccation, of course, reduces the condition.

Distension due to histological fixation, a familiar problem, may be avoided by opening up the body cavity before fixation or by dropping the animals into water at 65° C. for 15 sec. as a preliminary to chemical fixation. Apart from the avoidance of distension, the histological picture is considerably improved by these methods. Heat-treatment denatures the proteins (judged by opacity) throughout the body and presumably inactivates a water-absorbing mechanism. The most powerful chemical fixatives fix only exposed and thin-walled structures, such as the gills, the rate of penetration into the body being too slow to effect fixation or to prevent fluid distension. It seems probable that the gills are important in the control of water balance.

In such Crustacea as amphipod *Mimonectes*, a pronounced distension of the body would seem to be a normal adaptation to a specialized mode of life.

Morphology of *B. megatherium* Bacteriophage

MUCH attention is at present being paid to the fundamental problem of the relationship between the viruses and their host cells. The action of bacteriophage on bacteria is in many ways analogous to the action of a virus upon an animal cell. Since the bacterium-bacteriophage system is the less complex, and more amenable to electron microscopical study than living cells, the mechanism of bacteriophage action is a subject of active research.

It has already been shown by Luria, Delbrück and Anderson[1] that the T_2 coliphage is sperm-shaped, and hence easily identified in electron micrographs. The *Salmonella pullorum* and *Rhizobium leguminosarum* bacteriophages have also been shown to have a similar morphology[2,3]. In this laboratory, we have recently found that the No. 1 phage of *B. megatherium* also possesses a readily identified sperm-like structure. The large size of the *megatherium* bacillus makes it readily visible in the light microscope under oblique illumination, and the action of phage on this organism has already been discerned with the light microscope[4].

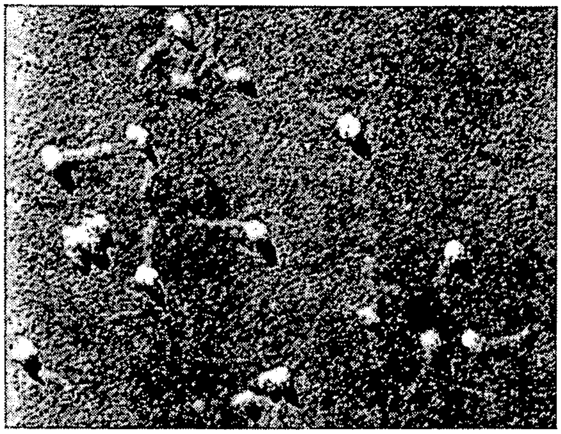
Material. Cowles described[4] the characters of two phages, isolated from sewage and designated No. 1 and No. 2, active against seven different strains of *B. megatherium*. The phages were inactivated by heating to 75° C. for 10 min. Further observations[5] on strain of *B. megatherium* No. 899 (De Doreen de Jong) showed that bacteriophage could be demonstrated in filtrates of cultures developed from spores heated to 90° C.

A culture of *B. megatherium* No. 1 isolated in 1904 and a quantity of phage No. 1 were received from

Dr. Cowles, and concentrated preparations of phage were prepared as follows.

Technique. Broth culture of *B. megatherium* incubated at 37° C. for 5 hours was inoculated on 2 per cent nutrient agar plates, and allowed to dry. Thereafter 1/200 c.c. volumes of phage were placed on the surface of the inoculated media, allowed to dry, incubated at 37° C. for 24 hours, and lysed areas transferred with a loop to broth. The suspension of phage was centrifuged at 2,500 r.p.m. for 30 minutes, to deposit vegetative forms, and the supernatant removed. After repeating this procedure eight times, a concentration of No. 1 phage active to a dilution of 10^{-6} against *B. megatherium* No. 1 was eventually attained.

This suspension was centrifuged in narrow flat-type tubes (3 mm. by 10 cm.) in the Swedish angle centrifuge at 4,200 r.p.m. for 2 hours, and the deposit was resuspended in a few drops of saline. Electron microscope mounts were made on 'Formvar' films and rinsed in distilled water to remove salt after the customary manner. The mounts were then shadow-cast with about 50 A. of chromium at such an angle that shadow-length to object height ratio was 3·5 : 1.



Results. The accompanying photograph shows a group of *megatherium* phage photographed on an R.C.A. model EMU microscope without an objective diaphragm. Using a microscope calibrated by the use of a grading replica, our measurements show that the circular head of the phage is approximately 100 μ in diameter and 40 μ high. The 'tail' is 260 μ long by 40 μ wide. It will be noted that the tail is flat and somewhat undulating in comparison with the straight rod-like tail of the T_2 coliphage. *B. megatherium* is one of the larger bacteria susceptible to phage action, and its No. 1 phage probably one of the largest bacteriophages.

Two New Antarctic Leeches

I should like to give here a short preliminary note upon two new antarctic fish leeches. A paper on them has been prepared, but as printing conditions in Norway at present are very difficult, rather a long time may pass before it will be published.

Trulliobdella capitis n. g. n. sp. was collected from *Parachænichtys georgianus* (Fischer) and *Chænocephalus bouvetensis* Nybelin. A paper on the latter fish is in the press. The leeches were located to the dorsal part of the fishes' heads, between the eyes. The parasite is dorso-ventrally flattened, showing two body regions, a shorter and more slender præclitellar part, and a postclitellar part which is twice as long and broad. Eyes are present on the oral sucker as well as on the most anterior annuli. The normal somite possesses three primary and six secondary annuli. The mouth opening of the cup-shaped oral sucker is subterminal; the stomach is without posteriorly directed gastric cæca. A 'fold organ' is inserted between the intestine and the rectum. Somital vascular lacunæ are found outside the dermal musculature. The length of the animal is 10–39 mm. As the present species cannot be grouped within any hitherto known genus, a new genus had to be established. Its nearest relatives seem to be the genera *Pterobdella*, *Pterobdellina* and *Phyllobdella*, as these genera are characterized by the absence of posteriorly directed gastric cæca. On the other hand, it seems related to the genus *Branchellion*, because both genera show a 'fold organ' between the intestine and the rectum.

Cryobdellina bacilliformis n. g. n. sp. was collected from the oral cavity of *Parachænichtys georgianus* (Fischer). There can be no doubt that this leech is closely related to the genus *Cryobdella* Harding, 1922. Common characteristics to both genera are the presence of four testes sacs, the arrangement of posteriorly directed cæca, the diminutive size and the antarctic distribution. As the present species, however, possesses eyes, both on the oral and posterior sucker as well as on the most anterior annuli, and four distinct lateral intestinal pouches, it cannot be assigned to the genus mentioned, and a new provisional genus had to be established. A further characteristic of the animal is the central position of the mouth in the bell-shaped oral sucker, the latter being heptagonal in outline because of dorso-marginal short broad papillæ. Only two specimens were at my disposal, and both seem not to be fully mature, as questionable signs of ovisacs only could be traced. Four pairs of testes sacs were, however, present. The length of the animal was 7–8 mm.

Wild and Cultivated Rice

The systematics of rice is, as systematists will agree, a matter of more than academic or departmental interest. The improvement of this important cereal depends on its sound classification. To this end the remarks of Dr. D. Chatterjee[1] seem to fall short of what is needed.

One part of Dr. Chatterjee's article consists of unacknowledged verbatim extracts from the first two chapters of a popular essay written twenty years ago by the late Harold Peake[2]. The passages on the "three successive stages of civilization", "hunting in packs", and so on, might have been taken from Horace or Lucretius. And the transcribed account of "recent discoveries in India", although more up to date, is no longer appropriate to Mohenjo-daro.

The work of Vavilov published in 1926 is referred to by Dr. Chatterjee. Here the disadvantage of relying on what Peake wrote in 1928 becomes serious. It is not the most recent of Vavilov's works, nor does it deal with rice as his later work does. Dr. Chatterjee might, however, have noticed one point in this early paper of great significance: Vavilov's account of *Triticum* establishes the principle in systematics (already well understood in genetics at that time) that chromosome numbers, where they vary, must be a basic criterion in the classification of plants.

Not since 1918 has anyone attempted to discuss the species of wheat without reference to their chromosome numbers. It is due to this fact that the classification of *Triticum* is now so well agreed and its application to breeding, to problems of fertility and sterility, and of hybridization and selection, so fruitfully practised.

Now, since 1936, the species of rice, like those of wheat, have been known to fall into inter-sterile groups defined by their chromosome numbers. Our knowledge of the genus is still fragmentary, but the following points seem to emerge. There are two groups of species, diploid and tetraploid. Each of them contributes types cultivated both for grain and for fodder; and the tetraploid group extends from East Africa, where Dr. Chatterjee has omitted to map *Oryza eichingeri*, to the Philippine Islands, where the grain rice *O. minuta* is cultivated[3].

To these matters Dr. Chatterjee makes no reference. Yet, whether for estimating ancestry, or raising posterity, or even for the more recondite tasks of comparing spikelets and discovering synonymy, it is important to know whether the plant one is dealing with is *O. eichingeri* with 48, as opposed to *O. eichingeri* with 24, chromosomes. It is more important even than to know whether one is dealing with *O. eichingeri* Peter, as opposed to *O. eichingeri* Paul!

What we need to know now, in rice as in many other groups, is whether the herbarium names in fact belong to the living plants which have been found to have particular chromosome numbers. When Dr. Chatterjee has procured these "much-needed data" we may be able to apply his botanical observations to some useful purpose.

[3] Darlington, C. D., and Janaki Ammal, E. K., "Chromosome Atlas of Cultivated Plants" (London: Allen and Unwin, 1945).

MY article on the wild and cultivated rices was originally prepared at the request of the Economic Botanist, Assam, who is contemplating writing a popular book on rice. Owing to the special nature of my assignment, and also due to my limited knowledge of cytogenetics, I had to restrict myself to the morphology of the rice spikelet and preparation of a key to the species and their enumeration and synonymy. This was stated in the beginning of my article. The published summary in *Nature* essentially deals with this part of my effort, and the omission of cytological discussions and the chromosome numbers of the species of *Oryza* was intentional. This aspect of the subject is being dealt with by my friend in Assam, from other sources. As such, my article, for obvious reasons, was meant to deal only with a particular portion of the problem and should be judged on its own merits. I agree with Dr. Darlington that the chromosome numbers, wherever available, should be given. This enables us to have a better idea of a species and its affinities with other allied species and genera. But whether the chromosome numbers should be all-important and should form the basis of classification in plants is a subject open to controversy between the cytologists and the taxonomists. As a taxonomist, I believe that a natural system of classification of plants based on synthetic methods over a long period has fairly, and within reasonable limits, stood the test of cytologists.

Vavilov's essays on the origin of cultivated plants and Peake's book on the origin of agriculture were of general interest and were freely consulted. A small portion from the latter book was used in a modified form, and in an effort to avoid a large number of inverted commas in a connected text of few lines it was thought fit to acknowledge the book at the end. This has been duly done in the second list of reference books given in my article.

The omission to plot *Oryza eichingeri* in East Africa in the map is very much regretted. This was accidental and I am grateful to Dr. Darlington for directing attention to it. This will be corrected in the fuller paper.

Maturation of Megaloblasts in Bone Marrow Cultures

INVESTIGATING the effect of folic acid upon the maturation of megaloblasts, we used a modified bone-marrow culture method of Osgood. During our experiments we saw megaloblasts ripen not only in media containing folic acid, but also in those which contained only the prescribed Osgood medium (65 per cent Gey solution and 35 per cent serum obtained from placental vein). Supposing that the placental serum might contain certain substances responsible for cell growth, in the next stage of our experiment we used normal adult serum instead of the placental one. To our surprise we found that megaloblasts ripen even in these conditions. (At the beginning, the megaloblast ratio of all nucleated red blood corpuscles was 50 per cent, 48 hours later only 8 per cent.) In the third stage of our experiments we further modified Osgood's method and used sera obtained from patients suffering from pernicious anæmia. We had every reason to suppose that normal serum might contain the anti-anæmic factor, which is absent in pernicious anæmia sera. Hence, we put the bone marrow simultaneously into vessels containing normal, and others containing pernicious anæmia sera, both prepared under the same conditions as above. The surprising result was that megaloblasts ripened in the pernicious anæmia medium too, although to a lesser extent. (Example: decrease of the relative number of the megaloblasts in 48 hours from 50 to 18 per cent.)

We suspected—rather boldly—that the megaloblasts in the media containing pernicious anæmia serum ripen less perhaps because there is an inhibitory factor which is diluted by the Gey solution. In the next experiment we changed the proportions, using as medium 65 per cent pernicious anæmia serum and only 35 per cent Gey solution. The result was that no ripening of megaloblasts took place (37·5 per cent at the beginning and 36·5 per cent after 48 hours). Our supposition seemed to be justified, so in the next experiments we made the following parallel cultures: 35 per cent normal serum and 65 per cent Gey solution; 65 per cent normal serum and 35 per cent Gey solution; 35 per cent pernicious anæmia serum and 65 per cent Gey solution; 65 per cent pernicious anæmia serum and 35 per cent Gey solution. Every experiment had a double control and in each case we used the same marrow for the different media. The results were: megaloblasts ripened better in concentrated than in diluted normal sera, but much less (or not at all) in concentrated than in diluted pernicious anæmia ones.

We conclude, therefore, that: (1) folic acid acts directly upon the megaloblasts; (2) pernicious anæmia serum seems to contain an inhibitory substance exerting its effect upon the ripening of the megaloblasts. Its degree of action depends upon the concentration or dilution of the pernicious anæmia serum in the marrow cultures.

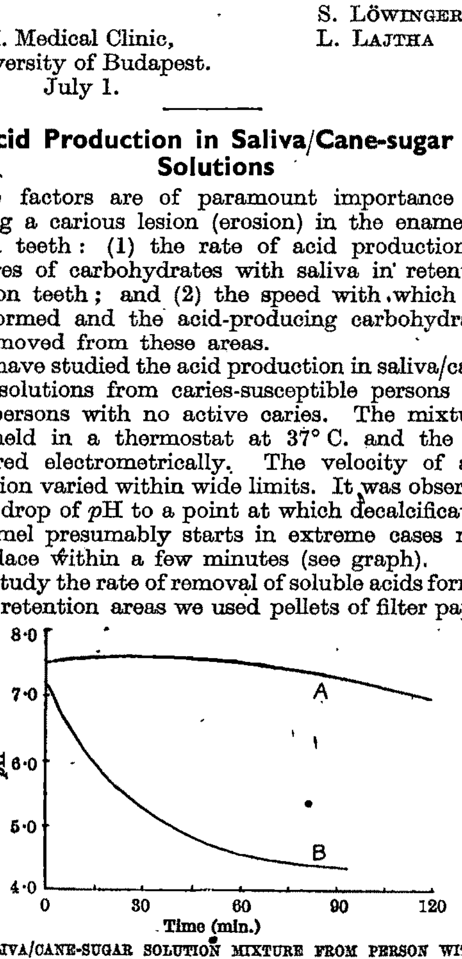
Acid Production in Saliva/Cane-sugar Solutions

Two factors are of paramount importance for starting a carious lesion (erosion) in the enamel of human teeth: (1) the rate of acid production in mixtures of carbohydrates with saliva in retention areas on teeth; and (2) the speed with which the acid formed and the acid-producing carbohydrates are removed from these areas.

We have studied the acid production in saliva/cane-sugar solutions from caries-susceptible persons and from persons with no active caries. The mixtures were held in a thermostat at 37° C. and the pH measured electrometrically. The velocity of acid formation varied within wide limits. It was observed that a drop of pH to a point at which decalcification of enamel presumably starts in extreme cases may take place within a few minutes (see graph).

To study the rate of removal of soluble acids formed in the retention areas we used pellets of filter paper, dyed in a water-soluble dye, pressed in between the approximal surfaces of teeth. We have found that after two hours without any food or drink intake, more than 50 per cent of the dye was washed out.



A, SALIVA/CANE-SUGAR SOLUTION MIXTURE FROM PERSON WITH NO ACTIVE CARIES; *B*, SALIVA/SUGAR-CANE SOLUTION MIXTURE FROM PERSON WITH RAMPANT CARIES

After centrifuging salivas or filtering through ordinary paper filters, the centrifugates were found inactive. The precipitates, however, gave when mixed with cane-sugar solutions a surprisingly rapid acid formation.

On the basis of these observations, it is evident that the elements in saliva capable of producing acid rapidly after incubation with cane-sugar solution are concentrated in the precipitating masses (mucin, epithelial cells, leucocytes, micro-organisms, etc.). The rate of acid production is so rapid that we doubt very much whether this process is caused, as hitherto suggested, by the activity of micro-organisms; we believe it is probably due to an enzyme system already present in saliva.

In persons with slow acid production in saliva/cane-sugar solutions, we have at times of intermittent illness found the rate of acid formation greatly accelerated; in such cases 'normal' values are reached fairly rapidly during convalescence.

Effects of Anterior Pituitary Extract and Hypophysectomy on Blood-Sugar Levels after Injection of Alloxan

Kirschbaum, Wells and Molander[1] find that alloxan hyperglycæmia does not occur but is replaced by fatal hypoglycæmia in fasting rats from which the pituitary gland had been removed, either immediately before, or 72 hours before, injection of alloxan. Houssay, Orías and Sara[2], using recently hypophysectomized toads, say that alloxan hyperglycæmia is not abolished by hypophysectomy. Martínez and Orías[3] find that injection of alloxan induces some degree of hypoglycæmia in normal rats and in rats hypophysectomized six days previously. Normal blood-sugar levels in both cases were regained 48 hours after injection.

Experiments in this laboratory show the disagreement in the literature is due to: (*a*) different periods of time elapsing between operation and injection of alloxan; (*b*) failure to take into account the glycostatic function of the anterior pituitary gland; (*c*) insufficient number of, or no, control operations. This latter criticism also applies to experiments of Kirschbaum *et al.*, and Goldner and Gomori[4] on adrenalectomy and effect of alloxan, and may explain the disagreement between their results and those of Houssay *et al.*

The animals used in the present work were inbred hooded rats weighing between 100 and 150 gm. and wild rabbits obtained as 200–300 gm. kittens and raised in the laboratory. Hypophysectomy was carried out on rats under 'Avertin' anæsthesia. Control operations consisted of the same procedure, except that drilling ceased before the pituitary was reached (sham-operated). Completeness of removal of the pituitary was checked at autopsy in all cases, and the results from incompletely hypophysectomized animals rejected. Rats were fasted 24 hours before injection of alloxan, and rabbits 17 hours. Under these conditions it was found that intraperitoneal injection of 200 mgm./kgm. of alloxan brought about no change in blood-sugar level of the intact hooded rat 4 hours after injection. On rats sham-operated 24 hours previously, blood-sugar values ranging from marked hypoglycæmia (43 mgm. per cent) to marked hyperglycæmia (352 mgm. per cent) were found four hours after injection of alloxan. Rats hypophysectomized 24 hours previously were consistently hypoglycæmic (average value of 49 mgm. per cent) four hours after injection. However, it is difficult to see on what statistically permissible grounds the figures for the sham-operated group can be averaged and the figure compared with the mean figure for the hypophysectomized group. It would appear that some factor other than hypophysectomy alone is involved in the hypoglycæmia of the hypophysectomized group. These results indicate that, in rats, operations carried out a short period before commencement of the experiment cause unpredictable changes in blood-sugar level after alloxan, which invalidate the experiment.

If, however, the rats were allowed to recover from the operation for a period of eight days, those subjected to the sham operation were normal in that they showed no blood-sugar change four hours after intraperitoneal injection of 200 mgm./kgm. of alloxan. These had apparently recovered from the effect of the operation and behaved like intact rats injected with alloxan. Those rats subjected to the operation of hypophysectomy eight days previously, whether receiving alloxan or control injections of water, showed to a similar degree the well-known spontaneous hypoglycæmia of fasting hypophysectomized animals (average of 63 mgm. per cent for the alloxan group and average of 47 mgm. per cent for group receiving water). This spontaneous hypoglycæmia is due to lack of the glycostatic action of the anterior pituitary.

The effect on blood-sugar levels after injection of alloxan of the opposite procedure to hypophysectomy, namely, pretreatment by parenteral injection of anterior pituitary extract, was studied in rabbits. The extract used was an alkaline extract of fresh ox anterior lobes made according to the method of Young[5]. Pretreatment consisted of three subcutaneous injections of the extract at 24, 17 and 3 hours before injection of alloxan. Total pretreatment dose was equivalent to 5 gm. fresh anterior lobes. The results fell into two groups according to the weight of the animals. In rabbits weighing 800 gm. or more, pretreatment with anterior pituitary extract resulted in a much greater hyperglycæmia (average figure of 160 mgm. per cent at two hours after intravenous injection of 200 mgm./kgm. of alloxan) than in rabbits not pretreated (average figure of 110 mgm. per cent at two hours). The onset of hypoglycæmia was delayed in the pretreated rabbits. Using the T test, the difference between the average curve for the pretreated rabbits and that for the untreated rabbits was significant ($P > 0\cdot05$).

In rabbits weighing 500 gm. or less, slight hyperglycæmia appeared in the pituitary pretreated animals after intravenous injection of 200 mgm./kgm. of alloxan. This hyperglycæmia (average figure of 113 mgm. per cent at two hours) was then followed by marked hypoglycæmia, but in the untreated controls only hypoglycæmia (average figure of 67 mgm. per cent at two hours) without preliminary hypoglycæmia appeared. The difference between the average curve for the pretreated rabbits and that for the untreated rabbits was significant ($P > 0\cdot02$), as was the difference between the average response for untreated 800 gm. rabbits and untreated 500 gm. rabbits ($P > 0\cdot01$).

Further work is in progress on this enhancement of alloxan hyperglycæmia, and a detailed report will be published at a later date.

Sound Emitted by Dolphins

With reference to Dr. Kullenberg's observation in *Nature* of November 8, p. 648, on sounds emitted by dolphins, the following quotation from Capt. Parry's "Journal of a Voyage for the Discovery of the North West Passage", 1821, is relevant. It concerns the white whale (*Delphinapterus leucas*), p. 35. "Mr. Fisher described them to be generally from 18–20 feet in length; and he stated, that he had several times heard them emit a shrill, ringing sound, not unlike that of musical glasses when badly played. This sound, he further observed, was most distinctly heard, when they happened to swim directly beneath the boat, even when they were several feet under water, and ceased altogether on their coming to the surface."

In *Natural History*, January 1940, p. 19, there is an account of observations on dolphins kept in captivity at the Marine Studios, Florida. The writer, Arthur F. McBride, gives a description of the sounds emitted by dolphins while under water and their use as a means of communication.

During the voyage of the Danish *Atlantide* Expedition to West Africa, 1945–46, dolphins were heard to make noises under water on several occasions. These were described to me by Dr. A. F. Bruun of the University Zoological Museum, Copenhagen, as being high-pitched whistles. The sound was outside the upper limit of my range of hearing.

That dolphins are sensitive to high-pitched notes is supported by another observation made while I was in the *Atlantide*. On December 30, 1945, a school of about a hundred *Delphinus delphis* was near the ship in calm water, splashing, diving and leaping vertically out of the water. The dolphins suddenly dashed away at great speed and their disappearance coincided with the switching on of the ship's supersonic echo-sounding machine. This sensitiveness to supersonic emissions was confirmed on a later occasion.

Dr. M. Burton of this Museum and I, in company with Major H. W. Hall, the owner of the yacht *Manihine*, watched common dolphins for a few minutes under ideal conditions this summer in the eastern English Channel. The dolphins could be clearly seen swimming under water and we observed that, intermittently, a stream of fine bubbles issued from the blowholes of the animals while they were still submerged to a depth of a fathom or two. None of us heard any emission of sound, but the possibility is suggested that it may be connected with this phenomenon.

PHYSIOLOGICAL EFFECTS OF ALKYL POLYPHOSPHATES

By A. S. V. BURGEN and C. A. KEELE
Department of Pharmacology
MARY CHENNELLS, J. del CASTILLO, W. F. FLOYD, D. SLOME
AND
PROF. SAMSON WRIGHT
Department of Physiology, Middlesex Hospital Medical School

DURING the War, the Germans introduced as insecticides a series of phosphate esters, including tetraethylpyrophosphate and hexaethyltetraphosphate. From information supplied to us by Mr. B. Topley, it appears probable that both these materials, in the form in which we have used them, were, in fact, mixtures of substances with the empirical composition implied by their names; in any event, it is certain that hexaethyltetraphosphate is almost instantaneously largely hydrolysed in water into simpler bodies. In toxicity tests[1,2] a characteristic syndrome of hyperexcitability, twitching, salivation and convulsions, has been noted with doses of 1–3 mgm./kgm. Dubois and Mangun[2,3] showed that these compounds are potent anticholinesterases; they are more active than diisopropylfluorophosphonate in the rat both *in vitro* and *in vivo*; this finding has been confirmed on the American roach[4].

We have examined the action of hexaethyltetraphosphate and tetraethylpyrophosphate on isolated organs in a number of species and on various systems in cats.

Action on the isolated tissues. The effects of hexaethyltetraphosphate were studied on the frog rectus abdominis muscle, the perfused rabbit heart and the rabbit and guinea pig small gut. With small doses no direct action was observed; but a progressive sensitization of the organ to acetylcholine occurred until only 1/10–1/100 of the dose of acetylcholine previously required to produce a given response was effective. The effect of this smaller dose of acetylcholine was nearly always prolonged; that is, cardiac slowing or arrest persisted for much longer periods and the gut relaxed more slowly on washing. A detectable effect first appeared with concentrations of hexaethyltetraphosphate of 10^{-8}–10^{-7} (2×10^{-8}–2×10^{-7} *M.*) and reached a peak at 10^{-6}–10^{-5} (2×10^{-6}–2×10^{-5} *M.*). The potentiation produced by hexaethyltetraphosphate persisted for at least six hours despite repeated washing out; indeed, this potentiation was always greatest after washing out the hexaethyltetraphosphate several times. In concentrations of 10^{-4}–10^{-3} *M.*, hexaethyltetraphosphate produced direct effects on the test organs. The guinea pig gut and frog rectus progressively contracted; the rabbit's heart slowed and decreased in force; the rhythmic contractions of the rabbit intestine increased in amplitude, and the resting tone rose. The rise in tone was initially annulled by atropine, but later the tone continued to rise despite atropine. Hexaethyltetraphosphate produced maximum potentiation of acetylcholine action in concentrations two hundred times smaller than is the case for diisopropylfluorophosphonate. Tetraethylpyrophosphate produced similar qualitative effects to hexaethyltetraphosphate; its action was greater but more transient; thus on the guinea pig gut some recovery was noted in 1 hr. Triethylorthophosphate in 100–1,000 times the concentration of hexaethyltetraphosphate produced a marked depression of the rabbit heart, and a small potentiation of the action of acetylcholine on the other organs (equivalent on the guinea pig ileum to 1/400 of that of hexaethyltetraphosphate).

Action of hexaethyltetraphosphate in the chloralosed cat. The toxicity syndrome on intravenous injection of hexaethyltetraphosphate in increasing doses was as follows:

0·025–0·1 mgm./kgm.: no detectable effect.

0·2–0·3 mgm./kgm.: slight bradycardia and slight fall of blood pressure.

0·4–0·6 mgm./kgm.: marked slowing of the heart (to half the initial rate) and fall of blood pressure (of 60–100 mm. mercury), which began to recover after 10–20 min. Respiration was stimulated; marked salivary and bronchial secretion, micturition and excessive bowel movements with defæcation occurred. The pupils were usually dilated, but the nictitating membrane was not retracted; sometimes pupillary constriction occurred. Muscle fasciculation and minor convulsive movements were seen and the animal responded markedly to jarring.

0·8–2·0 mgm./kgm.: almost immediate violent convulsions; very marked slowing of the heart and fall of blood pressure (to about 40 mm. mercury); profuse salivary and bronchial secretion, vigorous gut movements and defæcation. The animal's condition rapidly deteriorated and death usually occurred in less than one hour.

After atropinization most of the visceral effects were abolished and doses up to 100 mgm./kgm. were given intravenously without producing serious visceral or respiratory changes.

Tetraethylpyrophosphate produced similar effects in comparable doses; triethylorthophosphate produced no systemic effects.

Action of hexaethyltetraphosphate on response to peripheral stimulation of vagus (cat). In control experiments supramaximal stimulation at 1, 2, 4, 10, 25, 50/sec. produced graded slowing of the heart and fall of blood pressure. After giving hexaethyltetraphosphate the maximum immediate effect of a given stimulus was only increased by 10–40 per cent, but the recovery period was much prolonged. On stimulating at 10/sec. for 5 sec. the area under the blood-pressure and heart-rate recovery curves was doubled by 0·2 mgm./kgm., quadrupled by 0·4 mgm./kgm. and increased 10–20 times by 0·8 mgm./kgm. These effects lasted for at least 6 hr. 0·4 mgm./kgm. of hexaethyltetraphosphate caused a 2–4 fold potentiation of the bradycardia produced by intravenous acetylcholine. After 2 mgm./kgm. of hexaethyltetraphosphate the animal became completely unresponsive to vagal stimulation; whereas 0·1 μgm. of acetylcholine had previously produced a marked fall in blood pressure, no response was obtained until 2 mgm. of acetylcholine was injected, when a small rise of blood pressure occurred.

Effect of salivary secretion. A marked flow of saliva occurred on injection of 0·4 mgm./kgm. of tetraethylpyrophosphate even after the chorda tympani had been cut; during this time no increase in salivary flow occurred on stimulating the peripheral end of the nerve; when this spontaneous flow ceased the response to nerve stimulation returned to its previous magnitude.

Effect on nictitating membrane. The response of the nictitating membrane to peripheral stimulation of the cervical sympathetic trunk was unchanged until 1 mgm./kgm. of hexaethyltetraphosphate was injected, when some potentiation occurred.

Conjunctival application of 1 drop of 1 per cent hexaethyltetraphosphate solution constricted the pupil.

Effect of intravenous hexaethyltetraphosphate on the nerve muscle response in chloralosed atropinized cats. The popliteal nerve was stimulated with maximal shocks from a thyratron and coil once every 2·5 sec.; the response of the gastrocnemius-soleus muscle was recorded (*a*) mechanically by a torsion lever on a smoked drum, and (*b*) electrically from belly-tendon leads. Doses of hexaethyltetraphosphate smaller than 0·2–0·3 mgm./kgm. had no apparent effect. Further doses of the order of 0·5 mgm./kgm. had a marked potentiating action on the nerve muscle response. The mechanical response increased by 40–80 per cent, was maintained for some minutes slightly below peak level, and than gradually returned to normal. Action potentials showed no increase in amplitude but a repetitive response developed, consisting of one or two additional synchronous discharges, followed by an asynchronous discharge of smaller amplitude which persisted for about 100 m.sec. The control synchronous action potentials had a duration of 10 m.sec. The nerve muscle potentiating doses of hexaethyltetraphosphate had very little effect on blood pressure and produced only slight fasciculation. Further increase in the dose of hexaethyltetraphosphate produced additional potentiation followed by depression of the nerve muscle response; as the dose was still further increased, the initial potentiation became less and the subsequent depression more profound. Doses of hexaethyltetraphosphate of the order of 2 mgm./kgm. were purely depressant. Doses (0·5 mgm./kgm.) which potentiated the response of the nerve muscle preparation reversed a 90 per cent depression of the nerve muscle response caused by a previous appropriate dose of a curare preparation ('Intocostrin'). Essentially similar effects on the nerve muscle responses were produced by tetraethylpyrophosphate.

Action of hexaethyltetraphosphate on spinal reflexes. This was studied in decerebrate and chloralosed cats with and without atropine. The reflexes examined, namely, knee-jerk, flexor reflex and crossed extensor reflex, were generally initially potentiated; these changes were accompanied by variable degrees of fasciculation of peripheral origin. Increase of resting extensor tone and convulsions, sometimes violent and prolonged, were noted. A small increase in the dose of hexaethyltetraphosphate frequently converted increased reflex responses into depression. The effect of the drug was sometimes different on different reflexes; thus depression of the knee-jerk might coincide with potentiation of the flexor reflex. Convulsions have also been produced by tetraethylpyrophosphate; these were usually mild and transitory, but muscle fasciculation was very marked.

Intrathecal injection of hexaethyltetraphosphate produced with increasing doses an increased 'repetitive' knee-jerk (0·05 mgm./kgm.), increased crossed extensor reflex (0·4 mgm./kgm.), mild convulsions (0·6 mgm./kgm.) and increased resting extensor tone followed by very violent convulsions (4 mgm./kgm.). The initial phenomena were unaccompanied by any change in blood pressure or in the nerve muscle response. The very violent convulsions produced by the larger doses of hexaethyltetraphosphate were, however, at their peak, associated with an increase in the nerve muscle response, suggesting slight absorption of the drug into the general circulation. The hexaethyltetraphosphate convulsions were phasic, and sometimes a second burst of convulsions occurred when the nerve muscle response had returned to its control condition. The evidence indicates that hexaethyltetraphosphate (like diisopropylfluorophosphonate[5] and the tertiary anticholinesterases[6]) has a central excitant action on the spinal cord.

We are indebted to Mr. B. Topley for chemical information and to Messrs. Pal Chemicals for supplies of materials.

ETIOLOGY OF STRAWBERRY VIRUS DISEASES

By Dr. CONWAY A. WOOD and Dr. T. WHITEHEAD

STRAWBERRY virus diseases in Great Britain have hitherto been described mainly on the basis of the symptoms shown by the 'sensitive' variety Royal Sovereign[1,2], and are classified under the terms 'crinkle' and 'yellow-edge', each of which includes a wide range of symptom-intensity. It is now recognized that certain of the so-called 'tolerant' varieties, such as Huxley and Oberschlesien, also suffer degeneration due to virus infection, exhibiting symptoms which may resemble closely those of yellow-edge in Royal Sovereign[3,4]. The wild strawberry, *Fragaria vesca* L., owing mainly to its marked virus sensitivity, has been much employed as an indicator plant in the study of these diseases.

In investigations during the period 1938–45, we concentrated at first on an analysis of the virus entity causing 'severe crinkle' in Royal Sovereign, the complex nature of which had been suggested by earlier workers[5,6]. Efforts to segregate component viruses by (i) the use of possible differential insect vectors, (ii) comparison of aphis-transmission with graft-transmission, and (iii) the use of possible differential host plants were all unsuccessful, but a separation of 'non-persistent' and 'persistent' virus components was at length accomplished by daily transfers of infective aphides (*Pentatrichopus* (*Capitophorus*) *fragariæ* Theob.) along series of *F. vesca* indicators. Distinct symptomatological differences appeared between the first plants—that is, those colonized directly from the infector-plants on the first day of the experiment—and all subsequent plants. Both components were later retransmitted from *F. vesca* to other *F. vesca* plants, and to Royal Sovereign, both by graft- and aphis-transmissions. Evidence was obtained that separation of the components is not affected either by post-infection starvation of the vectors or by a sojourn of the latter on the virus-immune plant *Potentilla anserina* L.[4] between infection-feeding and feeding on the indicator plant, but is dependent solely upon lapse of time between these two feedings.

The results led us to the conclusion that plants of Royal Sovereign suffering from severe crinkle contain two viruses, one of which persists in the aphis vector for several days and the other for not more than one day. These results, however, were obtained only by the use of aphides which were reared on the Royal Sovereign infector plants. When similar experiments were conducted with aphides given only short infection-feeds (up to 4 hr.) the aphides remained infective only for a short time, and symptoms of the non-persistent virus type alone were produced in *F. vesca*. The persistent component either was not transmitted, or was retained in the aphides for no longer than was the non-persistent component. This agrees with the results of contemporaneous experiments at East Malling[7], in which aphides fed for short periods (up to 24 hr.) on certain infector plants, including 'severe crinkle' Royal Sovereign, transmitted only a non-persistent virus.

A beginning was later made in the analysis of other diseases met with in the field. It was found that 'mild crinkle' in Royal Sovereign most probably contains only a non-persistent virus, whereas both non-persistent and persistent viruses were obtained from Royal Sovereign affected with yellow-edge; from 'degenerate' Huxley showing yellow-edge-like symptoms; and even from a normal, vigorous, clonal stock of Huxley ('Malling 44'). It is considered that the virus components of yellow-edge in Royal Sovereign and of 'degenerate' Huxley are of similar type and are perhaps identical. The viruses in normal, vigorous Huxley (M44) and in a Royal Sovereign stock (M35) showing mild crinkle are also of similar type, but are probably not identical since only the former has given definite evidence of a persistent component. The persistent viruses isolated from 'degenerate' Huxley, from vigorous Huxley and from yellow-edge in Royal Sovereign, all appear to differ from the persistent virus in Royal Sovereign plants showing severe crinkle.

These tentative groupings were supported by the results of a later experiment with the variety Huxley. Degeneration was produced in plants of the M44 clone of this variety by colonizing them with aphides (*P. fragariæ*) reared on Royal Sovereign showing yellow-edge or on 'degenerate' Huxley or Oberschlesien plants (both showing symptoms resembling yellow-edge). Degeneration did not occur, however, where the aphides used had fed on Royal Sovereign showing mild or severe crinkle or on vigorous plants of Huxley or Oberschlesien. We at no time obtained evidence that the two latter varieties can carry, without symptoms, viruses capable of causing yellow-edge in Royal Sovereign.

In the course of these studies the symptoms of crinkle in Royal Sovereign and in *F. vesca* were analysed into 'unit characters', comprising reduction in size, distortion, leaf malformation, chlorosis and pigmentation, the varying proportions of which give rise to the wide range of symptoms shown by infected Royal Sovereign plants in the field. An appreciable variability in the clinical picture also occurs among plants of either *Fragaria vesca* or *F. moschata* Duch.—even though clonal—when these are infected with either mild or severe crinkle under conditions made as uniform as possible. Many carefully investigated examples led us to the opinion that symptom variability, especially in *F. vesca* but also in Royal Sovereign, is a function not only of virus content but also of the individuality of the plant in its reaction to a given virus, and that this is a factor to be taken into account both in fundamental research and in field surveys.

This work, a full account of which will be published later, was carried out at the School of Agriculture, University College of North Wales, Bangor, with the aid of a grant from the Agricultural Research Council.

PROGRESS IN ELECTRON MICROSCOPY

MORE than a hundred and fifty people, including visitors from the United States, Holland and France, attended the conference of the Electron Microscopy Group of the Institute of Physics which was held during September 16–17 at the University of Leeds. The meeting opened with addresses of welcome from the Vice-Chancellor of the University and from Prof. R. Whiddington; Sir Charles Darwin was in the chair.

The first session was devoted mainly to biological topics. Drs. R. Reed and K. M. Rudall (Department of Biomolecular Structure, Leeds), in a paper illustrated by many slides and enlarged micrograms, described work on gold-shadowed replicas of (*a*) the non-banded collagen-type fibres of the earthworm cuticle, and (*b*) the cell structure of striated muscle fibres from the frog. In the former case valuable information is provided on the manner of growth of the fibres and how they are arranged in layers of alternating fibre direction; while in the latter further details showing the organisation of the sarcolemma, sarcoplasm and striated myofibrils are clearly revealed. Investigations such as these, the results of which are now being reported from many countries, make it evident that the time is rapidly approaching when a new histology will have to be written.

Dr. V. E. Cosslett (Cavendish Laboratory) and his colleagues dealt with the preparation of bacteria for electron microscopic examination. Many cells are too opaque to show internal detail when using the 60 kV. beams of most present-day microscopes, but methods had been developed for rendering them more transparent, for example, by treatment with acetic acid vapour, ether vapour, or hydrochloric acid. Internal structures have also been revealed by light metal-shadowing, or by normal evaporation of metals on to the organism, or by the use of very thin supporting films of beryllium. Details of the preparation and handling of such films were given and photographs showed their obvious value in this type of study. Dr. N. E. Brieger (Papworth, Cambridge) further illustrated the methods by reference to the growth of avian tubercular bacilli on a solid medium. Dr. F. M. L. Sheffield (Rothamsted Experimental Station) described how certain plant viruses produce abnormal inclusion bodies in the cells of the host. By micrurgical methods some of these bodies have been isolated and examined in the electron microscope and their contents compared with other parts of healthy and infected cells. In cells infected with tobacco mosaic virus, the virus particles are located not only in the cell nuclei, but in other parts of the cell besides. In severe etch disease, an examination of nuclear and cytoplasmic inclusions revealed crystalline bodies, many of which show details of internal structure. In a paper by Dr. L. Dmochowski and Prof. R. D. Passey (Department of Experimental Pathology and Cancer Research, Leeds) and Prof. W. T. Astbury and Dr. R. Reed (Department of Biomolecular Structure, Leeds), extracts of normal and malignant tissues derived from mice of high and low breast-cancer strains were studied. Roughly spherical particles of about 200 A. diameter were found in the extracts of lactating breast tissues and of breast tumour tissues obtained from mice of three high-cancer strains. Extracts of lactating breast tissues and of experimentally induced breast tumours from mice of two low-cancer strains were found to be free of these particles. All extracts are being examined for tumour-inducing activity in susceptible mice, and the results of these tests are keenly awaited. [See also *Nature*, October 25, p. 565.] Dr. van Dorsten (Philips, Eindhoven) illustrated the possibilities in the use of high-velocity beams by showing photographs of yeast cells taken with electrons ranging from 70 to 300 kV. At the higher voltages there was surprisingly little loss of contrast, and internal detail was clearly seen.

The remainder of the session was devoted to problems of technique. Dr. A. E. J. Vickers (Imperial Chemical Industries, Ltd., Billingham) referred to various devices for simplifying the manipulation of grids covered with thin supporting films. The photographic methods employed at Billingham were mentioned; since the electron beam often adversely affects the specimen, photography after a fixed time interval is recommended to obtain comparable micrograms. Mr. M. E. Haine (now of A.E.I. Research Laboratories, Aldermaston) gave an account of the new Metrovick experimental microscope. The new model employs a three-lens system which allows a wide control of magnification (1,000–50,000 times at 50 kV.) with a great reduction in the size of the instrument. The pumping-out time from atmospheric pressure, even with the small diffusion pump used, is only about 2½ minutes. No air-locks are necessary, and a precision-made specimen stage of a robust design is thereby made possible. Improved electron gun performance gives usable image brightness even at the highest magnifications: at present the instrument operates at 50 kV., but higher voltages are allowed for in the design. The instrument was demonstrated at the Conference and was enthusiastically examined by a large number of visitors. A paper on asymmetry in electrostatic lenses and its correction was read by Prof. P. Grivet (TSF Laboratory, Paris). A theoretical treatment showed that lens asymmetry is due mostly to mechanical defects, and mention was made of a correcting device consisting of four solenoids spaced 90° apart which could be rotated about the axis of the lens. In discussion it was agreed that such a device would be successful, but doubt was expressed whether it would be easily workable. Dr. Bruck, of the same Laboratory, reported on a simplified form of microscope for the study of cathodic emission. The object surface (about 3 mm. in diameter) was easily changeable and could be heated to 2,500° C. by electron bombardment. Magnifications from 50 to 2,000 were provided by a two-stage electrostatic lens system, and preliminary results from various metallic surfaces were presented.

On September 17, Prof. W. T. Astbury was in the chair, and the time was devoted to problems of specimen examination. Dr. V. E. Cosslett (Cambridge) demonstrated that specimens exposed to the electron beam for some time often show a loss of contrast and considerable visible growth. These effects were especially strong on particles in direct contact with the specimen grids, but less noticeable on material supported on collodion or similar non-conducting films. Studies with different specimens on a variety of grids suggested that the effects arise from a contamination, partly from the specimen grid itself and partly from traces of organic material which are deposited on the specimen and grid. Where particle size is sought, Dr. Cosslett suggested the use of cleaned grids, a clean vacuum and specimens supported on non-conducting films. Photography in the central regions of the grid spaces was also recommended. Mr. I. M. Dawson (National Institute for Medical Research, Hampstead), in a study of the metal-shadowing technique, reported on the degree of gold aggregation occurring on different types of supporting film, as assessed by electron diffraction methods. The crystallite size of gold deposited on graphite films, for example, was found to be much greater than on collodion films. Evidence was given to show that direct shadowing of gold on to a specimen already mounted on a supporting film leads to more aggregation than if the metal is first deposited on the specimen and removed later by a stripping technique. It was considered that light metal-shadowing leads to less artefact production, and support was given for the contention that with metal-shadowed specimens further evaporation and deposition of metal may occur during examination in the microscope.

The Conference ended with a discussion on the most suitable choice of photographic material. Dr. R. Reed and Mr. A. Millard (Leeds) gave the results of testing a number of plates and films. Certain emulsions were mentioned as having ample contrast and reasonable grain size, yet showing a rapid response to electrons. The advantages of such fast emulsions were listed, the chief being that they minimize the risk of image movement during exposure. Particular emphasis was laid on the use of 35-mm. film, since the precision techniques of miniature photography can then be applied. In discussion it emerged that the high sensitivities quoted were in some way connected with small-grained emulsions of a high silver/gelatin ratio. Further tests on various plates and films were reported by Mr. I. M. Dawson, who also described a successful roll-film adaptor for use in the Siemens type of microscope. It was mentioned that when non-conducting materials are used in such electron cameras, attention must be paid to the problem of the dispersal of charge on the recording film.

In conclusion, it is gratifying to report that teething troubles in British electron microscopy are now more or less over, and that, so far as present conditions permit, the outlook is full of promise. Not only have the new techniques been learned; they are being actively applied and developed in the elucidation of many fundamental problems, particularly in the biological field. It may be claimed that the new Electron Microscopy Group of the Institute of Physics is now safely launched, and the growing membership and increasing vigour of its discussions augur well for the future.

More complete accounts of the contributions summarized above will be published elsewhere.

R. Reed

FORESTRY IN BRITISH COLONIAL TERRITORIES

IN the Forest Administration Report for Nigeria (Gov. Printer, Lagos, 1945; London: Crown Agents for the Colonies. 4*s*.) it is stated that in future the forest year will close at the end of March instead of at the end of December, due to the fact that at the end of December most of the forest work carried out in the cold-weather season is only half completed. In India the close of the forest year has always been March 31 for the same early recognized reason. The report in question, therefore, is dated from January 1, 1944, to March 31, 1945. In it we read that yet another revision of the forest policy of the Government was approved in February, 1945. The objects are briefly summed up. Since subsistence farming by a rapidly increasing population is the major industry of the country, the forest policy aims at preserving the climatic and physical condition of the country, its soil fertility and its water supplies by the maintenance and improvement of the vegetation cover, and at supplying in perpetuity and as cheaply as possible all the forest produce both as raw material and as the product of forest industries, required for the well-being of the inhabitants of the country.

Because of the growing demand in Nigeria for land for cultivation, it is essential that the forest estate should be secure, well distributed, and intensively managed, and that exploitation be controlled and improved and forest industries initiated and developed to prevent waste of land or produce. A ten-year plan of development detailing the staff and expenditure required to give full effect to the policy was submitted during the year, and is still under consideration.

Even before the War, but particularly during its preoccupations, inadequate staff has resulted in farming encroachments in reserves; so much so that a certain area of previously reserved forests has now been lost. It is said that as opportunities begin to increase for the necessary stock-taking, it has become depressingly obvious that only a much increased protective staff, firmer deterrents by adequate penalties in the courts and a more rigorous attitude on the part of Government in its reservation policy and practice will check these alarming forest depredations. Among other losses of forest, the Benin Native Administration has had to excise 396 sq. miles which have been so much farmed as to be no longer productive forest. In this connexion a remark is noted by the Conservator of Forests, N.E. Circle, on revisiting the area of the Benin Forest where he had practised sylviculture for some years. "I should like to place on record that I have never seen such extensive forest destruction anywhere to compare with that which has taken place in the unreserved forests of Benin Division during the last ten years. It is indeed fortunate that more than 50% of the forests of the Division have already been reserved. Forest reserves scarcely require to be demarcated now, because they stand out so prominently in the landscape." Other considerable excisions of so-called forest reserves have had to be made in other parts of Nigeria. The report states that: "The reserves, approved many years ago, have in numerous cases not been clearly demarcated and described, and they are steadily being whittled away by the encroachments of farmers. Persistent and continuous efforts to consolidate what remains of the forest, which is essentially the last local source of timber and fuel for a rapidly increasing population, have consistently failed. They will continue to fail if the Department cannot obtain administrative support in resisting the truculent demands of the improvident cultivators. There is admittedly very definite land hunger in this Province, but the relinquishment of all forest land for agriculture will not relieve the pressure for more than a few years, while the production of timber and fuel on land degraded by continuous cultivation and incapable of producing food will then be difficult and expensive."

In the Report for the Forestry Department, Nyasaland, to the end of December, 1945 (Zomba: Gov. Printer, 1946), it stated that the activities of the Department during the year were mainly devoted to maintenance and consolidation of progress already achieved. Proposals for planting schemes in various native areas, mainly for firewood production, were considered by several district development committees, and in most cases endorsed. It is thought that such short-term schemes can usually be financed either by native treasuries or by grants from the local native development and welfare fund. On the other hand, long-term schemes in native areas for the production of major timber will generally require assistance from funds provided under the Colonial Development and Welfare Act, 1945. A pre-requisite, however, for all further forestry development is an increase in the European staff and a local school for training Africans in forestry. An urgent need is to impress on the large African population the principle that payment will have to be made by the people for the ultimate produce derived from forest plantations, and that for the large majority of village communities the only alternative to planting schemes is for them to maintain adequate village forest areas (natural woodland) from which produce may be taken free of charge in return for the free communal labour given in the protection and simple management of the areas.

A committee was set up by Government to make recommendations concerning the legislation which is required to ensure the conservation and improvement of the natural resources of the Protectorate. Recommendations were submitted to Government in the form of a bill introduced at the session of the Legislative Council held in December. The proposed legislation has an important bearing on forest policy, and is greatly welcomed by the Forestry Department.

An interesting item of information of possibly considerable value in the future is contained in the following extract: "Certain areas of the Rift Valley escarpment in Dowa and Dedza district are assuming an increasing importance as a source of bamboos for commercial purposes, the manufacture of tobacco baskets being one of the main items. In order to effect greater control over this trade a bamboo market was established by the Department at Mvera on the Dowa escarpment, and its success was reflected in a great increase in sales of bamboos from the region. It is hoped to set up bamboo markets at other centres. Villagers, of course, come from afar to these escarpments to take bamboos free of charge for their own domestic requirements. Very large numbers of dead bamboos, following a gregarious seeding, are available for cutting in Mua-Livulezi forest reserve near the railway in Dedza district. Local demand is only small and undoubtedly there is scope here for commercial enterprise."

The Administration Report to the end of 1945 of the Conservator of Forests, Trinidad and Tobago (Gov. Printer, Trinidad, 1946), makes interesting reading. In some ways Trinidad has made considerable progress as compared with other forest services under the Colonial Office; not the least, perhaps, in the fact that a number of the forests of the country are under 'working plans' which provide some form of elementary yield control; and even in more or less inaccessible reserves of the Northern Range, which are not yet under working plans, girth limits are in force wherever exploitation takes place. Further, all 'working circles' subjected to concentrated regeneration are governed by working plans. The main factor which is brought about by this position is that the amount of excessive war fellings made during the last seven or eight years will be known and, if necessary, future exploitation regulated in the areas which have suffered, just as is the case in India. This reflects considerable credit on the forest administration of the Colony and the Colonial Government. There are one or two matters, however, in which the Forest Department does not appear as yet to have found itself. It appears to have come to the conclusion that imports of a certain type of forest produce will always be necessary, owing to the fact that exploitation of tropical forest is very costly, and that even the mora forests do not appear to offer great prospects as had once been hoped. On these subjects the report states as follows:

"Whilst the utilisation of local lumber generally has not yet reached the maximum production permissible, for supplies of properly seasoned lumber cut to a variety of standard dimensions, the Colony is dependent upon imports mainly of pitch pine, white pine and douglas fir. No supply of this type of local lumber is available other than small stocks held by furniture makers and private persons for their own use. Adverse factors such as the high cost of exploitation due to low volume production per acre, high loss in conversion of tropical woods, and high cost of labour in relation to skill and output render it unlikely that any such supply from the natural mixed forests could compete with imports. Expert opinion differs as to the economics of intensive exploitation of the mora forests, adverse factors being a high conversion wastage and the refractory nature of mora as a timber. The Colony is likely, therefore, to be dependent upon imports for the higher grade building market until the regenerated forests commence to yield regular supplies of timber at a high rate of volume per acre and consequent low cost of exploitation. Much more intensive exploitation of the forests could, however, be secured by the production of veneers for plywood manufacture. Before this can be undertaken, however, it is necessary to be sure of an adequate supply of raw material, which in turn depends upon how many of the local species will veneer satisfactorily."

In connexion with the introduction of the rotary saw or peeler of the plywood mill into the exploitation of the tropical forest question, it by no means appears necessary that a large percentage of the species of timber in the forest should be capable of peeling; it is not only the veneers from the more valuable tropical species that count, but also the poorer class timbers which are peeled to form the inner sheets; the veneers, of course, only occupying the outside. In any event, testing for peeling purposes of a certain number of the forest species should prove comparatively easy, as they could be sent to the Forest Products Research Station at Princes Risborough, or possibly to one of the United States research institutes. This would appear to be a practical piece of work which should be given early precedence.

Underlying most of the forestry reports from the British Empire at the present time is the recurrent statement stating that the departments are very much under-manned, and that really important work which should be put in hand to secure future progress must be held up until trained staff in sufficient numbers is available.

MUSICAL ACOUSTICS

CONFERENCE AT LIÈGE

In connexion with the recent celebrations of the centenary of the Faculty of Applied Science of the University of Liège and of the Engineers' Association connected therewith, a conference of persons interested in musical and dramatic acoustics was held during September 4–5 in that city. The sessions were held under the presidency of F. Dacos, and the arrangements were in the hands of F. Monfort. They consisted of five lectures by specialists in various aspects of the subject, followed by general discussions in which both men of science and musicians took part.

M. Fouché (Istambul) dealt with the theory of wind instruments. The natural frequencies of columns of air of various types—pipes with side-holes, partially stopped pipes, etc.—are worked out using the analogy with electrical circuits, the 'end-correction' appearing as a form of radiation resistance. For reed pipes the resonant frequencies of the system, reed plus column of air, are calculated and the results discussed in the light of the intonation of instruments like the clarinet. It was pointed out that these problems date back to some experiments performed by the brothers Weber in 1827.

G. van Esbroeck (Ghent) contributed a paper on the history of musical scales. He pointed out that it is not the ear which has dictated the series of tones which an instrument with fixed notes is made to produce; on the contrary, the tuning of such instruments has conditioned the education of the 'musical ear'. Thus our present scales are based on the Pythagorean tuning of the cithara, a stringed instrument of the ancient Greeks. The demands of key modulation, however, have forced a compromise with just intonation in the form of tempered scales. In the discussion that followed, it was pointed out that singers and players on free-note instruments like the violin use individual scales partly to suit the context or line of music and partly as a result of their musical education.

E. G. Richardson (Newcastle-on-Tyne) outlined the theory of coupled vibrations and of transient phenomena in the production of tone by musical instruments. The action of the hammer on a pianoforte string may be likened to the closing of an inductive switch in a primary electric circuit of which the secondary is a cable. The flute and the flue pipes of organs represent coupled systems in which the exciting member (the edge tone at the mouth) is very strongly damped in comparison with the other (the air column), whereas in an organ reed pipe, and still more in the human voice, the reverse is the case. In the first few milliseconds after the excitation of such a system, transients are set up, the wave form of which may be quite different to that of the steady state. The lecture was illustrated by oscillograms made by Dr. Richardson and his students.

L. Canac (Marseilles) described his work on the acoustics of open-air theatres. Tests of audibility of nonsense syllables have been made in the Roman theatres of Provence and in open country of similar rising contour. The theatre at Orange, in which the majority of the tests were made, has the stage complete with wall. Contrary to what has formerly been held, this backing wall does not act as a reflector to add intensity to the actor's voice but is so disposed, with much ornamental excrescence, to act as a diffusing screen; in fact, to simulate the conditions of the open air. This was confirmed by experiments on audibility at the theatre of Vaisons, where though the wall behind the stage has not survived, one can now hear better than at Orange, and by laboratory experiments in a model section, using ripples or supersonic beams to exemplify the diffusing properties of the irregular wall surface. Whatever the original intention, the actual function of the backing wall was, in Prof. Canac's opinion, to act as a screen to cut off street noise.

P. Fouché (Paris) gave a general account, from the scientific point of view, of the present state of the study of phonetics. The physicist plays his part by determining the relation between the timbre corresponding to different vowels and the shape and natural frequencies of the buccal cavities. The existence of fixed pitches (*formants*) corresponding to each vowel sound at whatever pitch it may be enunciated is now well established. The physiologist is concerned to measure the muscular effort required to enunciate and to maintain a speech sound—the latter is not constant but diminishes while the physical intensity remains steady. Psychology enters too, for the speaker often has a different 'feeling' for the rate at which he is using energy from that indicated either by muscular measurements or by a microphone measuring physical intensity. M. Fouché urged that the æsthetic aspects of speech should not be ignored. There is a beauty of language as well as a beauty of literature.

This concluded the discussions, but a visit was paid by those taking part in the meetings to the International Exhibition of Scientific Research and Industry, also held to celebrate the centenary, where of special acoustic interest was an electronic model of the ear, built and demonstrated by Dr. Coppée. This consists of a microphone connected through a number of filter circuits (to represent the resonant properties of the inner ear), each terminating in a thyratron and a flash lamp. The latter simulates the property of nerve fibres by which loudness is measured in terms of the *number* of messages passing per second to the brain. Thus, if one holds near the microphone a sounding tuning-fork of a frequency corresponding to that of one of the resonant circuits, the corresponding bulb begins to flash, and flashes become more frequent as the fork is brought nearer. The apparatus shows many other features of the sense of hearing. Gramophone records of music heard through the ear of a cat were also played.

At the final session, it was unanimously agreed that those present should form the nucleus of an international conference on acoustics generally, which should be called together every few years and held in a number of European centres in succession. The honorary liaison secretary for this purpose is M. F. Monfort, jun., 32 rue de France, Verviers, Belgium.

DANISH MARINE BOTTOM INVERTEBRATES

A RECENTLY published handsome volume*, dedicated to the memory of C. G. J. Petersen, director of the Danish Biological Station for many years, is in the best tradition of Danish oceanographical research, and is a tribute to the undaunted temper of the Danish people, who kept alive the spirit of learning, although surrounded by their enemies.

Petersen and Boysen Jensen had published during 1911–15 their "Animal Communities of the Sea Bottom", dealing with the charting of the fauna of the ocean bed from the Baltic to the Skagerrak by means of the newly invented Petersen grab. It was intended to follow this up by a study of the breeding habits and young of the bottom communities in relation to their importance as food for fishes, but between the Wars attention was diverted to investigations on the fish themselves. Dr. Thorson and his collaborators, many of them well known in the zoological world, began in 1936 an intensive study of the Danish marine fauna, but, "instead of concentrating on the young bottom stages", as Petersen did, have attempted "to trace the species back to the planktonic larval stages". It is here that our knowledge was deficient, yet research from the faunistic, economic or ecological points of view necessitates recognition of the species to which the pelagic larvæ belong. Despite the painstaking work of Mortensen on larval Echinoderms, Lebour on Molluscs and Crustacea and D. P. Wilson on Polychætes, most of us get no further than identifying an *Auricularia* larva, a Nudibranch egg ribbon, a zoœa larva or a Spionid metatrochophore. At first, then, much of Dr. Thorson's work was analytical. He must either rear the larvæ from eggs, as has been done so successfully at Plymouth, or trace the stages back to younger and younger larvæ, sketching every 'unknown' alive, in the hope that some day its place in the series will be found and its parents determined. Since these early stages are so sensitive to their environment, it is important to collect them in their own water, and to record temperature, light intensity, salinity, pH, food conditions and enemies. When all this has been done a synthesis from an ecological point of view can be attempted, involving all stages in the life of the animal and its community. "The whole survey," writes Dr. Thorson, "has been carried out in our leisure hours, and enabled us to combine the scientific work with splendid summer holidays."

The plan of campaign was to take vertical plankton hauls at metre intervals, from near the bottom to the surface, in fixed localities, every fortnight throughout the year. Two main sites were chosen, one off the island of Ven (Swedish) and the other at Helsingør (Danish). The former was used until 1941, after which date, owing to the War, the work was transferred to the Danish station. The net hauls were examined as soon as possible by a team of workers sorting, counting, sketching, recording and, if possible, identifying the species of animals. During the summer pump hauls were taken by pumping 200 (later 100) litres through a No. 12 plankton sieve, starting a few centimetres above the bottom, and repeating at metre intervals, so that nineteen samples were taken from the 20-metre depth of water. The advantage of this procedure was that the individual samples were transported to the laboratory in water from their own depths. Rearing of the larval stages was carried out in aquaria in the laboratory, and by means of 'bottle collectors' invented for the purpose. These were left submerged in the open sea, at the depth to which certain organisms were accustomed, for six weeks at a time, and then hauled up for inspection. The cage collectors used by Smith in Great Britain were found unsuitable owing to variations in temperature and salinity in Danish waters. The bottle collector is like an inverted bell jar, with a stopper at the lower end, protected at the sides by a jacket of pieces of cork held together by netting. It is anchored by stones to the required depth, and is marked by a float on the surface. This open apparatus collects its own sea bed for the delicate larvæ, from the rain of detritus from above, and experience shows that the larvæ are closely adapted to suitable surroundings, dying rather than metamorphosing if the right substratum is not available. The water in the bottle collects the swimming stages. Moreover, after being hauled up, the bottles can be placed on racks and kept as small aquaria. In one locality young bottom stages of seventy invertebrates were secured at a depth of 16 m.

---

* Meddelelser fra Kommissionen for Danmarks Fiskeri- og Havundersøgelser. Serie: Plankton. Bind 4. No. 1. Gunnar Thorson: Reproduction and Larval Development of Danish Marine Bottom Invertebrates, with special reference to the Planktonic Larvæ in the Sound (Øresund). Pp. 523+199 plates. (København: C. A. Reitzels Forlag, 1946.)

The results of these investigations showed that the dominant groups in the Sound plankton are Lamellibranchs (57·3 per cent), Prosobranchs (12·5 per cent), Polychætes (10·9 per cent) and Echinoderms (1·9 per cent). There is a high percentage of Cyphonautes larvæ (12·9 per cent), leaving only 4·5 per cent for all other groups.

Dr. C. B. Jørgensen contributes the section on Lamellibranch larvæ, and was able to identify twenty-three species, the most interesting of which were those of *Teredo* and the two species of *Montacuta*. Sixty-one Prosobranchs are known in the larval stage, and of these sixty have a long pelagic life. They are mostly phytotrophic and form the food of herring, mackerel and many invertebrates. About half the 142 species of bottom Polychætes can be identified in the larval stage, and their success in evading capture by predaceous animals is due to their armour of bristles. Many feed on the larvæ of Lamellibranchs. The percentage of Echinoderm larvæ appears small, until it is realized that these well-known larvæ cannot endure changes in salinity and temperature, and having no hydrostatic apparatus are unable to adjust themselves in depth when an infiltration of less saline waters from the Baltic floods the upper waters of the Sound. Dr. Mortensen considers that the parent stock on the bottom is recruited, not from the larvæ in the Sound itself, but from the large swarms of the Kattegat. He found also that the reproductive-rate of these migrants was less in the new habitat. This relation between spawning, larval survival and ecological conditions might be followed up around the shores of Britain in an attempt to explain anomalies of distribution.

Two life-histories that are of special interest are those of *Philine aperta* and the Holothurian *Psolus phantopus*.

In the final discussion many valuable generalizations emerge. Evidence goes to show that the larvæ are evenly distributed through the water masses, rarely swarming. In two years only three larvæ of *Strongylocentrotus drœbachiensis* were collected. Is this species, therefore, rare? Yet, if evenly distributed, there would be two and a half milliards in the area. What, then, must be the population of 'common' forms? Dr. Thorson works out that *Littorina littorea* would have twelve thousand milliard and *Mytilus edulis* four thousand five hundred milliard larvæ.

The distribution of the larvæ throughout the year enables one to work back to the spawning periods. July has the maximum for all types of larvæ in the Sound, but there are lesser peaks in spring and winter. The minimum is in the late autumn. Compared with fjord conditions, spawning is spread over a long period, not concentrated into a late spring and early summer peak as in the fjords. In the Sound there is a drift of larvæ from the Baltic northwards to the Kattegat, bringing impoverished specimens from the less saline waters. The reverse stream, from the Kattegat southwards, is much richer in individuals. There are also the larvæ developing from the spawn of animals living on the bottom. Analysing these three sources, Thorson found that the Baltic stream from May onwards brings chiefly the larvæ of *Littorina littorea* and other Prosobranchs, the bottom fauna of the Sound produces non-pelagic larvæ or larvæ with a short pelagic life (for example, *Serpula*), and the parents in the Kattegat provide 50 per cent or more of the whole stock in the Sound, mostly larvæ with a long pelagic life. As an ecological area, therefore, the Sound supplies very different data from those obtainable in either arctic or tropical regions, where the larvæ have mostly a short pelagic life; and in the temperate zone it is the high proportion of larvæ with a long pelagic life which provides food for the fishes of economic importance. Moreover, this is the group that shows the greatest fluctuation in numbers from year to year.

To sum up, Dr. Thorson's book is a valuable contribution to both analytical and synthetic aspects of the fauna of a marine area. We in Britain can learn much from his work and his methods, and not by any means least from his clear, smoothly flowing English and delicate, accurate drawings.

There is a summary at the end of each section, and the final summary is printed also in Danish. An exhaustive bibliography and index are appended. The book is well produced and printed, but its limp covers will soon need replacement in libraries.

N. B. EALES

FORTHCOMING EVENTS

Monday, December 1

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Anniversary Meeting.

Tuesday, December 2

SOCIETY OF DYERS AND COLOURISTS, SCOTTISH SECTION (at St. Enoch Hotel, Glasgow), at 7 p.m.—Dr. K. W. Richmond: "Modern Trends in Hydrogen Peroxide Application".

SOCIETY OF DYERS AND COLOURISTS, HUDDERSFIELD SECTION (joint meeting with the ROYAL INSTITUTE OF CHEMISTRY, at Field's Café, Westgate, Huddersfield), at 7.30 p.m.—Dr. W. Baird: "Modern Developments in Synthetic Detergents".

Wednesday, December 3

PHYSICAL SOCIETY, COLOUR GROUP (in the Lecture Theatre of the Geological Museum, Exhibition Road, London, S.W.7), at 3.30 p.m.—Mr. J. Pryce-Jones: "Ultramarine—Natural and Synthetic".

HISPANIC AND LUSO BRAZILIAN COUNCILS (at Canning House, 4 Upper Berkeley Street, London, W.1), at 5 p.m.—Mr. Kenneth G. Grubb: "The Great British Explorers of the Interior of South America".

INSTITUTION OF ELECTRICAL ENGINEERS, RADIO SECTION (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. T. C. Macnamara, Mr. A. B. Howe and Mr. P. A. T. Bevan: "The Design and Operation of High-Power Broadcast Transmitter Units with their Outputs Combined in Parallel".

MANCHESTER STATISTICAL SOCIETY (at the Reform Club, King Street, Manchester), at 5.30 p.m.—Dr. George Gibson: "Modern Distribution of Industrial Activity in the North-West Region".

Society of Public Analysts and other Analytical Chemists (joint meeting with the Food Group of the Society of Chemical Industry, at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 7 p.m.—Discussion on "The Occurrence, Physiological Importance and Estimation of Metallic Contaminants in Foodstuffs".

Thursday, December 4

Chemical Society, Sheffield Section (joint meeting with the Sheffield University Chemical Society, in the Chemistry Lecture Theatre, The University, Sheffield), at 5.30 p.m.—Prof. G. R. Clemo, F.R.S.: "The Bearing of the Isotopes of Carbon, Hydrogen, Oxygen and Nitrogen on Organic Chemistry".

Institution of Electrical Engineers (joint meeting with the Acoustics Group of the Physical Society, at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Dr. W. G. Radley: "Speech Communication under Conditions of Deafness or Loud Noise".

Chemical Society, Nottingham Section (in the Chemistry Lecture Theatre, University College, Nottingham), at 6 p.m.—Scientific Papers.

Illuminating Engineering Society, Manchester Centre (in the Reynolds Hall, College of Technology, Manchester), at 6 p.m.—Mr. W. Imrie-Smith: "Industrial Lighting".

Institution of Mechanical Engineers, Graduates' Section (at Storey's Gate, St. James's Park, London, S.W.1), at 6.30 p.m.—Mr. K. M. Fantom: "Electronics for the Mechanical Engineer".

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Sir Ian Heilbron, F.R.S.: "Recent Developments in the Vitamin A Field" (Pedler Lecture).

Society of Chemical Industry, Chemical Engineering Group (joint meeting with the Bristol Section of the Society of Chemical Industry, at Bristol).—Mr. A. Forster and co-authors: "The Manufacture of Tetryl by Continuous Nitration".

Friday, December 5

Institution of Electrical Engineers, Measurements Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Economics of Metering" (to be opened by Mr. M. Whitehead).

Institution of Mechanical Engineers (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Dr. E. A. Watson: "Fuel and Combustion Systems for the Aero Gas Turbine".

Geologists' Association (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Prof. D. M. S. Watson, F.R.S.: "Fossilization".

Royal Statistical Society, Industrial Applications Section (at the E.L.M.A. Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 6 p.m.—Mr. E. C. Fieller: "The Mathematics Division of the National Physical Laboratory, with particular reference to Statistical Methods".

Society of Chemical Industry, Manchester Section (joint meeting with the Local Sections of the Chemical Society and the Royal Institute of Chemistry, in the Lecture Hall, Albert Hall, Manchester), at 6.30 p.m.—Sir Wallace Akers: "Industrial Uses of Atomic Energy".

Manchester Statistical Society, Industrial Group (in the Society of Architects' Room, Textile Institute, 16 St. Mary's Parsonage, Manchester), at 6.45 p.m.—Mr. J. Morley: "Some Statistical Experiments in the Steel Industry".

Society of Instrument Technology, Midland Section (at the Chamber of Commerce Buildings, New Street, Birmingham), at 7 p.m.—Mr. V. A. Hughes: "Some Examples of Instrumentation in Modern Research".

Saturday, December 6

British Mycological Society (at the Linnean Society of London, Burlington House, Piccadilly, London, W.1), at 12 noon.—Annual Meeting; at 2 p.m.—Prof. C. G. C. Chesters: "Concerning Fungi Inhabiting the Soil" (Presidential Address).

Royal Institute of Chemistry, London and South-Eastern Counties Section (at the University, Reading), at 3 p.m.—Prof. E. A. Guggenheim, F.R.S.: "The Atomic Nucleus".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant in the Chemistry Department—The Secretary, Royal (Dick) Veterinary College, Summerhall, Edinburgh 9 (December 1).

Assistant Laboratory Technician in the Histological Laboratory—The Registrar, The University, Liverpool (December 6).

Chemical Pathologist in the Department of Pathology and Bacteriology—The Secretary, Welsh National School of Medicine, 10 The Parade, Cardiff (December 6).

Technical Assistants in the Pasture Research Branch of the Department of Agriculture and Lands—The Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (December 10).

Advisory Officer in Crop Husbandry—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (December 12).

Algologist (Scientific Officer) at the Millport Laboratory—The Secretary, Scottish Marine Biological Association, 185 St. Vincent Street, Glasgow, C.2 (December 13).

Senior Physicist with experience in textile research, a Senior Organic Chemist with experience in textile research, a Physicist with research experience, though not necessarily in textiles, and a Chemist for physical chemical research—The Director of Research, British Jute Trade Research Association, Bellfield Street, Dundee (December 20).

Junior Observer—The Director, The Observatories, Cambridge (December 20).

Assistant Pomologist, and an Assistant Plant Physiologist, at the Long Ashton Research Station—The Secretary and Registrar, The University, Bristol (December 27).

Naturalist at the Dove Marine Laboratory—The Registrar, King's College, Newcastle-upon-Tyne (December 31).

Travis Research Fellowship in Bacterial Metabolism in the Medical School, University of Otago—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (Otago, December 31).

Research Fellowship for the study of properties of natural and synthetic fibres—The Registrar, The University, Leeds 2 (January 1).

Head of the Applied Nutrition Department—The Secretary, Rowett Research Institute, Bucksburn, Aberdeenshire (January 3).

Assistant Lecturer (Grade III) for the Department of Brewing and Industrial Fermentation—The Secretary, The University, Edmund Street, Birmingham 3 (January 12).

Professor of Physiology—The Secretary, Queen's University, Belfast (January 17).

Lecturer in Diploma Mathematics (Post Matric. standard), a Lecturer in Physical, Organic, Inorganic and Industrial Chemistry and Chemical Engineering, a Lecturer in Diploma Physics (Post Matric. standard), a Lecturer in Electrical Engineering, a Lecturer in Mechanical Engineering, and a Lecturer in Civil Engineering, in the Technical Education Branch of the Department of Public Instruction of New South Wales—The Official Secretary, New South Wales Government Offices, 56–57 Strand, London, W.C.2 (January 25).

Assistant Director, Royal Botanic Gardens, Kew—The Secretary, Ministry of Agriculture and Fisheries, 23–25 Soho Square, London, W.1 (January 31).

Lecturer in Geology—The Registrar, University College, Hull (January 31).

Assayer or Chemist with special experience in the analysis of non-metallic and metalliferous minerals—The Secretary, Mianraí, Teoranta, Four Provinces House, Harcourt Street, Dublin.

Lecturer in Histology and a Lecturer in Biochemistry—The Registrar, King's College, Newcastle-upon-Tyne.

Assistant Chief Pharmacist by the Government of Malayan Union for Medical Department, Singapore—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.N.18288.

Research Worker (Junior, temporary) in Chemotherapy and Tropical Medicine at the National Institute for Medical Research—The Secretary, Medical Research Council, 38 Old Queen Street, London, S.W.1.

Metallurgist by the Ceylon Government for the Department of Commerce and Industries—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.N. 14681.

UNIVERSITY EXPANSION IN GREAT BRITAIN

IN the note on University Policy and Finance in Great Britain which the Vice-Chancellors and Principals Committee issued last July, the need for some overall planning of available resources as between the different universities of Britain was recognized by the official heads of the universities. The first need at the moment is a vigorous defence of the main programme of university expansion, and most important, on lines which will permit the development of teaching and research facilities to a point which will provide for the increase in the number of graduates called for by the Barlow Report and elsewhere. It is no less important that closer attention should be given to the question of exactly how and where that expansion should take place. The Committee of Vice-Chancellors and Principals has already accepted the view that the Government not only has the right but also the duty to satisfy itself that every field of study which in the national interest ought to be cultivated in Great Britain is, in fact, being adequately cultivated in the university system, and that the resources which are placed at the disposal of the universities are being used with full regard both to efficiency and to economy. Furthermore, it believes that the universities may properly be expected, collectively as well as individually, to devise and execute policies calculated to serve the national interest.

From this point of view, the recent conference of the universities of Great Britain (see *Nature*, October 18, p. 522) was disappointing. It is true that it is something that institutions of such strong independence and diversity of age and constitution should have been brought together to discuss common problems ; but it is no less true that what the conference revealed was not a large measure of common purpose but a marked preference for each university to deal with its own problems independently. The universities of Great Britain are clearly unaccustomed to thinking of themselves as a group ; and in spite of many admirable pronouncements from individuals, there is little evidence that the universities as bodies have yet realized that they are, or could be, a single force in the life of the community.

This lack of unanimity had several untoward consequences. It gave a certain air of unreality to the whole proceedings, but especially to those at the first session, dealing with the expansion of the universities. Even with Sir Alan Barlow in the chair, that discussion seemed in a world apart from the world economic crisis ; for no one ventured to face the possible effects of that crisis, direct or indirect, on university expansion, and what revision in capital expenditure would be possible, if called for, with the minimum handicap to expansion.

No doubt if the new Chancellor of the Exchequer, in the midst of his manifold responsibilities, can give any personal attention to the details of capital grants to the universities, they should have no cause to fear unreasonable calls for retrenchment. Sir Stafford

Cripps should be better able than most Ministers to appreciate the importance of the contribution of the universities to the efficiency of British industries and the production drive. But there will be no harm done if the universities are brought to realize that expansion may have to take place by austerity standards in order that the needs and standards of learning may be maintained.

Though expenditure on university education is an outstandingly rewarding investment for the nation, it was unwise for the universities to miss such an opportunity of a united testimony. Moreover, even if the recurrent grants to the universities are unaffected by the crisis, the expenditure, if not the amounts of the capital grants, may be modified. Halls of residence and some other building schemes may have to go lower on the list of priorities. Further, if the targets for increasing numbers are not to be lowered, especially the provision of teaching facilities, any reduction in capital expenditure will require careful adjustment and probably of a type that is almost impossible without close co-operation between the universities.

The conference maintained that the existing planning organisations are adequate, and this was a main reason for the rejection of the proposal for the establishment of a representative universities council. That might be true but for the existence of such independence or non-co-operation as was apparent at the conference. The emphasis placed by the conference on university freedom was, in fact, misplaced. The real dangers to university independence and freedom to-day may lie as much within the universities themselves as outside their gates.

The Vice-Chancellors and Principals Committee has suggested that the University Grants Committee should undertake the task of overall planning and making the necessary surveys of all the main fields of university activity in Great Britain. General recognition of the admirable work which the University Grants Committee has done and continues to do is to be found side by side with two opinions in the universities themselves, as well as outside, whether even the reconstituted Committee will be adequate for its task. The Vice-Chancellors visualize the Committee as surveying the university system and offering advice and suggestions to the universities as it seems fit; but while the Vice-Chancellors admit that they are not in a position to judge finally as to the order in which priorities would best accord with the nation's needs, there must remain the doubt at least in the minds of those outside the universities as to how far a particular university would accept advice and suggestions from the Committee on matters which touch closely local interests or tradition.

Apart from this, there is the view to which *The Economist* has given expression, which regards the University Grants Committee as inherently liable to accept passively suggestions which may come from the universities and the Committee of Vice-Chancellors and Principals rather than take an independent line of its own. Admirable as is the idea of a quinquennial Treasury fund for capital expenditure suggested by the Vice-Chancellors and Principals in their note, it might well be accompanied by conditions designed to ensure that development is in line with national and not sectional requirements, so far as those needs can be foreseen.

It cannot be said, therefore, that the question of the authority and organisation for university development as a whole has yet been finally determined. But while this urgent problem is being considered, it is important that the breathing space which some restriction on capital expenditure affords should be utilized to determine as accurately as possible the quantitative expansion of students which is desirable. The Ministry of Labour and National Service has already set on foot an inquiry to obtain as complete an analysis as possible of the existing distribution in age-groups and subjects of scientific and technical workers in Great Britain and overseas (see *Nature*, Nov. 29, p. 742).

Such surveys are manifestly required to supplement and to particularize the estimates both of the Barlow Report and the Percy Report, which were not entirely complementary; but more will still be required, as was indicated in the more recent Urwick Report, to cover the absorption of arts as well as science graduates in the administrative side of industry. There is room here for further surveys alike by the university appointments boards, the appointments bureaux of the professional organisations and by the Ministry of Labour and National Service; and they should be implemented at once so that their findings are available before the restrictions on expansion likely to be imposed by the general limitation of capital expenditure to £20,000,000 of building within the next five years can cease to be effective.

The survey recently completed by the Federation of British Industries* shows that industry is making a real attempt to formulate its own quantitative demands for research workers and technologists. This survey estimates that about forty-five thousand persons are employed directly on industrial research and development in industry, of whom about ten thousand possess a university degree or an equivalent qualification. These include mathematicians, physicists, chemists, biologists, engineers, metallurgists and others; nearly half are chemists and one third are engineers. Plans for the immediate future, to the end of 1947, indicate that half the firms who replied to the questionnaire will require additional qualified staff amounting to an increase of about twenty-five per cent, and the general trend of the replies indicates that a further increase of the same order will be required for 1948–50. The greatest numerical requirements are for chemists (839) and for engineers (494), but greatest proportional increases are for biologists (167) and physicists (252).

One of the first points that emerges from any such survey is the impracticability of considering university expansion apart from that of the technical colleges. Unless the anomaly in the higher educational system of Great Britain which places the development of universities and of colleges of technology under different Ministers is to be corrected in the near future, some other means of securing the necessary co-ordination must be devised as a matter of urgency. This is shown up even on the side of scientific man-power. With all the limitations of the present colleges of technology, it is estimated by the Parliamentary and Scientific Committee that between them they could have an output of between 5,000 and 7,000 trained technologists and scientific workers a year as against the 3,000 estimated for 1943 by the Percy Committee. This number cannot wisely be doubled without regard to the concurrent doubling of the output of science graduates from the universities, or indeed without regard to the output of arts graduates. At the present moment, as Lord Simon has pointed out, the relatively greater ease of expansion on the arts side of the universities has permitted the output of graduates in arts to rise more rapidly than the output of science graduates, and the problem of employment for arts graduates is already viewed with some concern. Important as it may be that there should be a proper balance between the different faculties in university expansion, there is a serious danger if the output of arts graduates is allowed to exceed to any considerable extent the probable demand for their services. Large-scale unemployment among university graduates has repercussions which are the more dangerous in that they are not immediately visible.

---

* Scientific and Industrial Research in British Industry: a Statistical Survey by the Industrial Research Secretariat. Pp. 20. (London: Federation of British Industries, 1947.) 1*s*.

An obvious first precaution is the compilation of reasonably accurate estimates of demand, and in this urgent task the Higher Appointments Department of the Ministry of Labour and National Service and the Technical Personnel Committee should receive every assistance that the professional organisations and the university appointments boards can give. However, it also raises more fundamental questions as to the purpose and content of university education itself, and whether in general it tends to be standardized too much in terms of the past. Lord Lindsay of Birker has stated that businesses are more and more going to the universities not just for men trained in the technical aspect of business but for men trained in problems of management, welfare and the like; and that local education authorities confronted with the expansion of the social services are asking more and more for men trained in the universities to deal with all kinds of problems concerned with the social services. Lord Simon also suggested that there are many administrative positions in which university men trained to bring imagination and breadth of view to bear on a situation may provide something that is often lacking in branches of industry and of local government. Even if the traditional avenues for the employment of arts graduates were not contracting rather than expanding, we are brought here face to face with the question whether the arts degree is to be regarded as in some measure a preparation for employment rather than for life.

The same fundamental issues were discussed at the recent Dundee meeting of the British Association in the discussion on the education of the man of science, and there is much to be gained if the different aspects are considered not in isolation but as particular aspects of one problem. Closer consultation between the different parties concerned and further exchange of views between competent and representative bodies will be required; and also some measure of experiment with fresh measures is necessary. Lord Lindsay indeed urged, as one reason for the establishment of a new and independent committee to consider the long-range problems, that the University Grants Committee, by practice and constitution, is not necessarily the best body to review the whole framework of higher education with the idea, perhaps, of revolutionary change.

There is no question of the importance of expanding the universities of Britain, and the imperative need for the universities, collectively rather than individually, stating the case for expansion and indicating quantitatively so far as possible how that expansion is to be planned in relation to available resources. Temporary retardation of the rate of expansion may be no disadvantage if the opportunity is seized for experiment and for fundamental thinking about the issues involved. There must also be greater readiness and determination to deal with the problems of specialization and of departmentalism, a readiness to accept new groupings rather than the traditional arrangements of subjects, and to work out, if necessary, new means by which standards of intellectual discipline can be maintained and inculcated.

These are not tasks which can be left to any one body, whether it be the University Grants Committee, a universities advisory council, or a new Royal Commission. They require the close co-operation of those engaged in university teaching, research or administration, school teachers, professional associations, industrial scientists, administrators and many others. Above all, the tasks demand the sustained interest of all those individual citizens who, whether university graduates or not, have seen some vision of what is at stake, and who realize how much depends on the universities providing not merely trained intellects but also men and women of personality and character.

MICROPALÆONTOLOGY IN GEOLOGY

Principles of Micropalæontology

By Martin F. Glaessner. Pp. xvi+296. (Melbourne: Melbourne University Press; London: Oxford University Press, 1945.) 45*s*. net.

THE last few decades have seen the rise of micropalæontology to a position of considerable importance in geology, particularly in the quest for oil. The publication of Dr. Glaessner's book is therefore a welcome event; and its production in this handsome form during the recent World War reflects credit upon those responsible for its get-up.

Although it was the academic geologists who first realized the scientific value of microfossils, we owe the main developments in this field to the applied geologists, and particularly to the palæontologists employed in the oil and coal industries. A notable exception to this statement is provided by the remarkable output of literature on Pleistocene and recent spores and pollen which has enriched our appreciation of plant distribution and chronology, of climatology and orogeny, and even of prehistory and archæology.

The book has grown out of a series of lectures given by the author in the University of Moscow, and the author makes acknowledgments (*inter alia*) to the Anglo-Iranian Oil Company and the Standard Vacuum Oil Company (New York) for their interest as sponsors for the work.

The treatment of the subject is dominated by the point of view of the oil geologist, for whose purpose the Foraminifera are—and are likely to remain—by far the most important microfossils, not only because of their great vertical range (Cambrian to Recent) and wide dissemination in the marine strata, which form the greater part of the sedimentary record, but also because they show fine morphological distinctions which can be closely dated in geological time.

The text is divided into three parts. In Part 1, after a brief historical introduction (Chap. 1, pp. 3–6), the author gives a cursory treatment (Chap. 2, pp. 7–32) of different groups of animals which are represented as microfossils; also of the flagellates, diatoms and bacteria. The stratigraphical value of plant microfossils, especially of spores and pollen, is fully recognized; but as their study is a highly specialized branch of micropalæontology the author makes no attempt to deal with it in any detail. Chap. 3, pp. 33–57, which should be read with a brief appendix (Chap. 10, pp. 237–242) deals with the practical details of collecting and preparing, preserving and studying microfossils. Although mainly intended for the use of those working on the Foraminifera it contains practical hints which the palæobotanist, too, would find useful. There is no mention of that time-honoured formula of Schulze (maceration with nitric acid plus potassium chlorate, followed by alkali treatment) which has served the palæobotanist so well. Freshwater Tertiary sediments examined mainly for plant microfossils are known to have yielded occasional chitinous fragments of animals (chiefly insects and mites). This technique is perhaps worthy of trial on marine rocks which contain animal remains having chitinous parts, for example, trilobites, arthropods, etc. If critically studied on the lines of plant cuticles, animal chitins may be expected to yield further data of practical as well as purely taxonomic value.

Part 2 (pp. 58–194) gives in three chapters a detailed account of the palæontology of the Foraminifera, with an introduction of ten pages on the structure of the living organism. The classification of the group is discussed in detail, with numerous illustrations and analytical charts which bring out graphically the more important facts relating to the morphology, palæoecology, stratigraphical distribution and phylogenetic relationships of the different groups of Foraminifera. In an appendix (pp. 243–252) there is a synopsis of a revised classification of the group and of the geological ranges of the more important genera.

Part 3 is devoted to stratigraphic micropalæontology. In Chap. 7 (pp. 197–212) the sequence of microfaunas from Cambrian to Tertiary is reviewed, and Chap. 8 (pp. 212–226) treats at some length of the correlation of strata, both local and regional, on microfossil data. The role of microfossils in oil geology is explained in Chap. 9 (pp. 227–235), with special reference to the main oil-producing regions of the world.

There is a voluminous bibliography covering thirty pages, classified chapterwise, followed by an index of fourteen pages and a table giving the standard stratigraphical scale, conveniently placed on a folder at the end of the book.

As stated, the work is chiefly intended for the student of Foraminifera in the search for oil, and the main body of the volume could do very well as an advanced text-book on the Foraminifera. For these purposes, evidently, the book is bound to be of the greatest value.

In the preface the author expresses the hope that a handbook covering the whole field of micropalæontology may at some future time be produced by the co-operation of specialists in different branches of the science. It is much to be hoped that this suggestion will fructify, and bring together in a handy form the vast and rapidly growing literature on spores and pollen both for the use of the academic student and of those engaged in the practical problems of lignites, peats and coals, and oil.

It has recently been shown[1] that in freshwater sediments which are devoid of Foraminifera, for example, in the great Tertiary oil-bearing series in Assam (until recently regarded as practically unfossiliferous), plant microfossils have a potential stratigraphical value parallel to that of the Foraminifera in the case of marine sediments. The value of plant microfossils in structural geology has also been demonstrated in a striking manner by confirming the idea of a regional thrust in the Salt Range which has brought the Cambrian and other Palæozoic strata in the Punjab so as to overlie the Eocene Saline Series[2]. The use of pollen analysis in the investigation of glacier movements is a fine illustration of the possibilities of this technique, which Volkmar Vareschi[3] has ingeniously laid bare.

The science of micropalæontology strides forward with the vigour of its youth: the number of specially trained workers and specially equipped laboratories engaged in this field all over the world bear witness to its interest and importance. Dr. Glaessner's book will provide a further stimulus to this activity.

All students of geology, and oil geologists in particular, will be grateful to the author for this valuable presentation of a subject of increasing scientific as well as practical interest.

RECENT PROGRESS IN GENETICS

Advances in Genetics

Edited by M. Demerec. Vol. 1. Pp. xvi + 458. (New York: Academic Press, Inc.; London: H. K. Lewis and Co., Ltd., 1947.) 7.50 dollars.

If the first volume may be taken as a fair sample of what is to come, many biologists besides geneticists proper will extend a warm welcome to the new series of "Advances in Genetics", edited by Dr. M. Demerec. No one nowadays can be confident of accomplishing the Sisyphæan task of keeping up with the literature, except within a very narrow field, which can scarcely comprise more than one section of such a broad discipline as genetics. Yet it becomes clearer every day that even sciences which were conventionally considered quite distinct do, in fact, throw revealing gleams of illumination on to one another, and may suddenly coalesce in the most unexpected, but fertile, unions. In these circumstances, a vital part is played by critical summaries of recent progress, detailed enough to reveal what is actually known and what is merely guessed, yet concise enough to deal with an important topic in a compass which the busy specialist in other fields can find time to absorb. In the past, there have been few such reviews on genetical subjects; this lack the new series is designed to fill.

The first volume covers a wide range, dealing with both botanical and zoological topics. The authors are all American, and could scarcely be otherwise, not only because American biologists have made genetics one of their favourite fields and have taken an undoubted lead in its recent development, but also because their work was considerably less interrupted by the War than that of any other country. It is certainly symptomatic of one of the main trends of present American thought in genetics that a majority of the articles deals explicitly with evolutionary problems. Thus Babcock summarizes the very extensive work on speciation in the genus *Crepis*; Gordon discusses speciation in fishes, with especial reference to the distribution of genes in some wild populations of *Platypœcilus*; Mangelsdorf writes on the origin of maize and Stephens on that of cotton; Stebbings deals with the different types of natural and synthetic polyploids; and Spencer gives a full account of the investigations which have been made on the mutant genes occurring in wild populations of *Drosophila* species.

The unprejudiced reader cannot help admitting, perhaps with some disappointment, that no other organism can begin to compete with *Drosophila* as a betrayer of Nature's genetical secrets. The story which Spencer unfolds is restricted to one special aspect of our knowledge of Drosophilid evolution-in-the-making; he describes only the distribution of mutant genes, and omits, for example, the massive work of Dobzhansky and Wright on the natural chromosome inversions within a single species, the studies of Sturtevant, the Texas group under Patterson, and others on systematics and chromosome morphology, as well as the recent work on mating barriers and infertility mechanisms within the genus. But one has only to compare Spencer's review with that of Gordon on fishes to realize how much fuller is our understanding of the insect; and if the cytological part of the *Drosophila* story had been included it would be found not inferior even to the body of information which has been collected about such plants as maize and *Crepis*.

Of the non-evolutionary articles, two are agricultural: Attwood on the breeding of forage crops, and Shrode and Lush on cattle. Irwin gives an account, perhaps rather too condensed, of recent work in immunological genetics, which includes a welcome summary of his own studies on the inter-specific antigens in doves. Perhaps the most generally interesting of these articles, and one of the highlights of the book, is a long review by Sonneborn of the recent studies on Protozoan genetics, conducted mainly under his guidance. The discovery of the system of 'mating types' within the varieties of *Paramecium aurelia* made possible an analysis by means of cross-breeding, the first result of which was to clear up many obscure points in the general reproductive biology of this classical organism. Very shortly, however, results emerged which were of much more profound significance for biology as a whole. In the best analysed varieties of *Paramecium*, inheritance of many, if not all, characters is primarily through cytoplasmic factors. A considerable amount has already been accomplished towards elucidating the extraordinary relations between the reproduction of these factors and that of the genes to which they are related; and by very ingenious methods of controlling the relative rates of reproduction, and the amounts of cytoplasm passed between the two individuals in conjugation, it has been possible to estimate that each cell may contain some 200–300 particles of one of the cytoplasmic factors. The importance of this line of work for our understanding of the relations between gene and cytoplasm, and thus for our theories of the most fundamental aspects of cell physiology, can scarcely be over-estimated.

C. H. WADDINGTON

BESSEL FUNCTIONS IN BULK

Tables of the Bessel Functions of the First Kind of Orders Zero and One

By the Staff of the Computation Laboratory. (Annals of the Computation Laboratory of Harvard University, Vol. 3). Pp. xxxvii+652.

Tables of the Bessel Functions of the First Kind of Orders Two and Three

By the Staff of the Computation Laboratory. (Annals of the Computation Laboratory of Harvard University, Vol. 4.) Pp. ix+652.

Tables of the Bessel Functions of the First Kind of Orders Four, Five and Six

By the Staff of the Computation Laboratory. (Annals of the Computation Laboratory of Harvard University, Vol. 5.) Pp. xi+652.

Tables of the Bessel Functions of the First Kind of Orders Seven, Eight and Nine

By the Staff of the Computation Laboratory. (Annals of the Computation Laboratory of Harvard University, Vol. 6.) Pp. ix+648.

(Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1947.) 55*s*. net each volume.

THE Computation Laboratory of Harvard University is equipped with an *IBM* automatic sequence controlled calculator, the construction and operation of which are described in Volume 1 of its *Annals* (see *Nature*, **158**, 567, Oct. 26, 1946). It was built with Bessel functions in the forefront of its programme, but has seen some war service. Now the calculation of these functions is—and despite its speed and ability to work 168 hours per week is likely for some time to remain—its 'base load'.

The four volumes before us are the first-fruits of its labours in this field. They contain values of $J_n(x)$ for $n = 0(1)9$ and $x = 0(0{\cdot}001)25(0{\cdot}01)99{\cdot}99$ (it is absurd that place could not be found for $x = 100$). The values for $n = 0, 1, 2, 3$ are given throughout to eighteen decimals, while those for higher values of n are given to ten decimals only.

The tables are entirely new, and are independent of all previous computation in this field. The 18-decimal values in volumes 3 and 4—or more precisely the 23-decimal values upon which they are based—form the foundation for subsequent volumes. In computing these use was made, for the smaller values of x, of the ascending power series (more accurately the Horner process applied to the polynomial which is the series truncated at a suitable term); but a change to the asymptotic series was made when x became large enough for this to yield the desired accuracy. The 10-decimal values in volumes 5 and 6 have been computed by a straightforward application of the recurrence formula. Details of the formulæ used, and of the elaborate checks applied, are given in an interesting introduction to volume 3. The machine prints its results by means of an electromatic typewriter, and it is these printed results which have been reproduced by photo-lithography, so that it is extremely unlikely that any errors will be found.

No direct provision is made to facilitate interpolation, but formulæ involving differences, and their Lagrangian equivalents (same order, different arguments), are given in the introduction to volume 3, while formulæ depending on the Taylor series, again reduced to Lagrangian form (same argument, different orders), are given in the introduction to volume 5.

The intention is to proceed with the computation of $J_n(x)$ for the same range of x as in the present volumes, for integer values of n up to and including 100. When the project is complete, all reasonable demands for values of the J Bessel functions of integer order would seem to be met. The 18-decimal values of volumes 3 and 4 constitute in themselves a fundamental table of major importance. If the engineer or physicist considers the provision of 18 decimal places absurdly generous, at least three replies may be made. It is easier to discard unwanted figures than to supply any desired beyond those given in a table; it is relatively inefficient to use a complicated machine at less than full capacity; to complete the project by the proposed use of the recurrence formula needs in the fundamental tables more than twenty decimals (the machine computes twenty-three) in order to secure everywhere ten *reliable* decimals.

We must be grateful for an achievement of such magnitude and enduring permanence, although one cannot help endorsing Dr. Comrie's wish that the resources of this computing engine had been deployed in fields where it could make significant additions to our knowledge.

But these large volumes—the page size is 7½ in. by 10½ in., and the four occupy together 7½ in. of bookshelf—inevitably bring to mind other questions. It is clear that in this machine we possess the means of 'mass-producing' the values of a class, limited but still very large, of mathematical functions: Computation, in this field, is no longer a crucial problem. It is now to the inter-related question of reproduction and accessibility of the results that some thought should be devoted. The volumes of the present project, when completed, will occupy some 5 ft. of bookshelf, but will cover only the J functions of integer order. Add also the I-, Y-, and K-functions, the Bessel functions of these types of half-odd-integral order, the *ber*, *bei*, and related functions in the Bessel family; then imagine the elementary functions, and the others which appear in, say, Whittaker and Watson's "Modern Analysis" treated equally generously. The size of the resulting library of mathematical tables becomes to a librarian frightening on the scores of both space and finance, and to the user embarrassing and forbidding.

Photographic reproduction from typescript, as used in these and other tables, has disadvantages which go some way to offset its evident advantages. Compared with good examples of tables printed from type the numerals are larger, but despite this are more fatiguing to use for any length of time. Most of the examples of mathematical tables photographically reproduced from typescript which the writer has seen are bulky owing to the use of relatively thick, absorbent paper; is this inevitable? Finally, is it impossible to harness modern computing machinery to some form of mechanical compositor, so that the advantages of appearance, legibility and compactness of the printed page may be combined with that saving of the labours of the compositor and the proof-reader which the method of reproduction of these volumes enjoys?

W. G. BICKLEY

SCHOOL BROADCASTING IN BRITAIN

School Broadcasting in Britain

By Richard Palmer. Pp. 144 + 27 plates. (London: British Broadcasting Corporation, 1947.) 3*s*. 6*d*. net.

AS Sir Henry Richards points out in a foreword to this volume, the publication of this "first considerable contribution" on the subject of school broadcasting requires neither apology nor explanation. Much has happened since the Carnegie Trustees undertook that pioneer investigation into the possibilities of broadcasts to schools, the results of which were made available in 1928 in "Educational Broadcasting: a Report of a Special Investigation in Kent". That progress should have been so rapid in the past twenty years is the more surprising when "the sceptical though benevolent neutrality" which characterized the attitude of educationists in the early twenties is recalled.

The task which Mr. Palmer has set himself is that of interpreting the work of his colleagues and himself; and it is one for which he is admirably equipped. A former lecturer in education in the University of Liverpool, he joined the staff of the School Broadcasting Department of the B.B.C. in 1940 and, in addition to a particular responsibility for science broadcasts, has had for seven years wide experience in the work of the department. His own contributions—which are made in ten chapters—are enriched by Miss Mary Somerville's account of "How School Broadcasting Grew Up", by Mr. John Horton's analysis of recent experiments in music, and by Mr. Edward Wall's discussion of modern language broadcasts.

Of particular interest to educational psychologists is the concluding chapter in which Mr. Palmer analyses "Some Problems for Study". It is, for example, assumed that school broadcasting can have a considerable influence on interests and attitudes. Of the short-term influence there is abundant evidence. But what of long-term interests? Do young people develop interests and hobbies in later life as a result of their introduction to such series as "General Science", "Science and Gardening", "Nature Study" and "How Things Began"? Interesting as this and other problems discussed by Mr. Palmer undoubtedly are, the most immediate need is, as he is well aware, for extensive research into the psychology of attention.

The Design of Experiments

By Prof. Ronald A. Fisher. Fourth edition. Pp. xi + 240. (Edinburgh and London: Oliver and Boyd, 1947.) 12*s.* 6*d.* net.

ONE of the striking characteristics of modern biological statistics is its insistence on experimental design. The most powerful methods of analysis can be used, and the greatest amount of information obtained, only if the experiment is laid out with this end in view. Randomization is necessary for trustworthiness, replication for efficiency and factorial design for comprehensiveness. Without these precautions, the experiment will at best give a poorer return than it need, for the labour and materials expended on it.

The first book devoted to the exposition of these modern principles of experimentation and their translation into design was "The Design of Experiments", the fourth edition of which has just appeared. This now standard work has been changed but little since its first appearance, and the only new addition, a valuable one, is a section on the fiducial limits of a ratio. The reappearance of this book will be welcomed by all who have an interest in biological experimentation.

K. M.

Wonders of Natural History

By E. L. Grant Watson. Pp. 192. (London: Pleiades Books, Ltd., 1947.) 8*s.* 6*d.* net.

THIS entertaining and attractively illustrated volume is a reprint of two earlier works, "Enigmas of Natural History" and "More Enigmas of Natural History". To the layman who reads for pleasure, and to the biologist who may read for profit, the author has much to tell that is curious, fascinating, wonderful and puzzling. That is the way of Nature, though we sometimes forget it. But at almost any point, in making casual observations on the life-history or habits of bird or insect, we are brought sharply face to face with the unknown, with phenomena on which the professed biologist so far has little positive to say. A realization of this prevailing state of affairs, an eye for telling examples, and a power of simple, lucid statement, are among the merits of the present work. At the end of almost every paper the author comes to the same point: How was this curious development or relationship brought about in the course of evolution? Is it conceivable that the many complex adaptations, each occupying its proper place and sequence in the individual life-cycle, are merely the result of continuous small variations, or even larger ones? These are still and always will remain topics of major interest in biology. It is good that we should occasionally be reminded of them.

Australia

Its Resources and Development. Edited by Prof. G. L. Wood. Pp. xvii+334+28 plates. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1947.) 20*s.* net.

MORE than a dozen authorities on various aspects of Australia have contributed to this survey of the economic resources and the prospects of the Commonwealth. In a short but sincere discussion on the peopling of Australia, "the general conclusion reached is that the growing period over three-quarters of Australia is not long enough for commercial agriculture". Much of it, however, is suitable for grazing of sheep or beef cattle. Several of the writers dwell on the problem of water, the risk of drought, the limitations of irrigation and the exploitation of artesian water. Water supply is, of course, linked with hydro-electric resources, which are abundant only in Tasmania and especially in New Guinea. The extent of mineral resources, fuel and possible industrial development are fully considered, and these as well as other problems are approached objectively and fully. Altogether this is one of the most valuable books on Australia that has appeared in recent years. It is illustrated with many photographs and maps.

Current Waterworks Practice

A Practical Treatise on the Provision of Water Supplies for Urban and Rural Communities. By W. H. Maxwell. Pp. viii + 254 + 20 plates. (London: B. T. Batsford, Ltd., 1946.) 21*s.* net.

THE increasing attention being given to the provision of wholesome water supplies to dwellers in country districts as well as in urban localities has prompted the author to prepare this very useful and practical treatise dealing in a generally comprehensive, and yet succinct, way with the various problems which arise in connexion with projects of water supply. It includes a discussion on a national water policy for rural and other areas, with transcripts of the provisions of the Rural Water Supplies and Sewerage Act, 1944, and the Water Act, 1945. The greater part of the work is of a practical and detailed character, commencing with a description of underground water resources and means for their conservation and protection from pollution, and then proceeding to discuss such matters as the choice of electric motors and other equipment for pumping installations; concrete and cement for constructional work, including the use of reinforced concrete; automatic pump control; methods of water purification and the sinking of wells. The volume is well illustrated by diagrams, and there are particulars and photographs of installations in Great Britain and abroad, showing current practice in reservoir construction. Among the appendixes is a useful statement of water equivalents and other data. There is a serviceable index.

B. C.

The Arboretums and Botanical Gardens of North America

By Dr. Donald Wyman. (Chronica Botanica, Vol. 10, No. 5–6.) Pp. 395–498 + plates 27–43. (Waltham, Mass.: Chronica Botanica Co.; London: H. K. Lewis and Co., Ltd., 1947.) 1.50 dollars.

OWING to the difficulty at the present time in obtaining factual information regarding staffs and equipment of scientific institutions, this account of the botanic gardens and arboretums of North America is welcome. Its survey deals with about ninety gardens of varying importance ranging from the New York Botanical Garden, the Arnold Arboretum, to smaller gardens connected with the botanical departments of universities and also those privately owned but open to the public.

In every case, the function, brief description of special features, ownership, size of collections, herbarium, budget, director, number of employees and list of publications are given.

In addition, a portfolio of prints and photographs of some of the more famous gardens, old and modern, American and foreign are given. There are also plans of some of the larger gardens. A very useful book of reference.

JUBILEE OF THE DISCOVERY OF THE ELECTRON

IN 1897, Prof. J. J. Thomson, working in the Cavendish Laboratory at Cambridge, discovered that cathode rays consist of negatively charged particles (electrons, as they afterwards came to be known) many times smaller in size than the smallest atoms known. During the fifty years that have elapsed since that discovery, it has been established that electrons form an essential part of all matter. Numerous practical applications of the use of electrons have been found, and vast new industries have been set up based on electronic devices. On the theoretical side, the discovery of the electron has opened the way to research into the structure of the atom, and, more recently, into that of the nucleus, leading finally, for better or worse, to the release of atomic energy.

To mark the jubilee of the discovery of the electron, celebrations were held recently in London by the Institute of Physics and the Physical Society in collaboration with the Institution of Electrical Engineers. On the afternoon of September 25, at the Royal Institution, Prof. J. A. Crowther gave a lecture on the history and early development of the discovery. He was followed by Prof. R. E. Peierls, who spoke on electrons in modern theoretical physics. In the evening, a public lecture was delivered to a very large non-technical audience at the Central Hall, Westminster, by Sir Clifford Paterson, director of the Research Laboratories of the General Electric Co., Ltd., on "The Electron Liberated". On the following day, the Electron Jubilee Exhibition at the Science Museum, South Kensington (see *Nature*, Oct. 4, p. 461), was formally opened. At the Institution of Electrical Engineers, a posthumous portrait of Sir J. J. Thomson, painted by Mr. Francis Hodge, was unveiled by 'J. J.'s' son, Sir George Thomson, who then addressed the assembly on the electron in research. He was followed by Dr. T. E. Allibone, who spoke on electrons in industry.

Prof. A. M. Tyndall, president of the Institute of Physics, in introducing Prof. J. A. Crowther, stated that the suggestion to celebrate the jubilee of the discovery of the electron had originated from a remark made by Dr. A. J. Maddock. The suggestion was taken up enthusiastically by the Board of the Institute of Physics, which then invited the Physical Society and the Institution of Electrical Engineers to join in the organisation of a series of meetings which would be thoroughly representative of the two sciences—physics and electrical engineering—which had been most directly affected by the discovery of the electron. Prof. Tyndall invited the meeting to send the following message of greeting to Lady Thomson, who was prevented from being at the meeting. "Representatives of science and industry, together with old friends, assembled at the Royal Institution to-day to commemorate the fiftieth anniversary of the discovery of the electron by your husband, send you warm greetings and best wishes."

Opening his lecture, Prof. Crowther said that in order to appreciate to the full the discovery of the electron and the genius of its discoverer, Sir J. J. Thomson, it was necessary to be aware of the ideas prevalent in the pre-electron era, and perhaps also the facilities available then. He therefore briefly outlined the position of physical knowledge in 1897 and the course of events which led up to Thomson's experiments. Prior to 1890, the study of electrical discharges in a vacuum tube had progressed very slowly, no doubt partly due to the extremely laborious methods of evacuation which had to be used, and also partly to the lack of serious examination of the beautiful phenomena observed. Schuster, in 1890, made the first real attack on the problem of elucidating the nature of the cathode rays, when he took the trouble to measure the magnetic deflexion of the rays in a measured magnetic field. The accepted view of British physicists at the time was that the cathode ray particles were atoms, so that the energy given to them by the electrical field would be all used up in driving the particles through the residual gas present in the discharge tube. Working on this assumption, Schuster obtained a value of 2,000 for the ratio of the charge e to the mass m of the cathode particle, a value which is consistent with the cathode particle being a nitrogen atom. The experiments performed by Hertz, Lenard and Perrin during the next few years did not help to clarify the situation, but provided rather conflicting evidence.

This was the baffling state of affairs when J. J. Thomson entered the lecture room of the Royal Institution on the evening of Friday, April 30, 1897, and delivered his now historic lecture on "Cathode Rays". Quoting from Thomson's lecture, Prof. Crowther showed how the results of Perrin's and Lenard's experiments were first carefully analysed by Thomson, leading him to the conclusion that "the size of the carriers must be small compared with the dimensions of ordinary atoms and molecules"; and then, further, how Thomson startled his audience with the bold and revolutionary conception that the atom has a structure which could be explored. By the October of 1897, Thomson was in a position to present, in the *Philosophical Magazine*, additional experimental evidence in support of his claims. This evidence included the now famous and elegant measurement of e/m for cathode particles. Finally, at the British Association meeting in 1899, Thomson announced that he had measured both e/m and e for the corpuscles emitted by a zinc plate when illuminated with ultra-violet light, thus identifying them with the cathode ray particles. From then onwards, as Prof. Crowther so tastefully expressed it, "the electron was accepted as a respectable member of society".

Prof. Peierls, who was introduced by Prof. G. I. Finch, president of the Physical Society, dealt with the effect which the electron, together with its associated fundamental particles, the positron, neutron, meson and neutrino, has had on the theoretical development of the laws governing the behaviour and structure of matter. The breakdown of classical mechanics led to the introduction of quantum theory and wave mechanics, with the consequent realization that the distinction between waves and corpuscles is not as fundamental as had been thought. In some respects the electron can behave as a wave, and in other respects as a corpuscle, particularly when it is moving slowly compared with the speed of light. The last remaining feature of the electron, its spin, was deduced by Uhlenbeck and Goudsmit from their work on atomic spectra. The consequences of these new laws have helped in the understanding of the structure of solids, the properties of metals and in particular the conduction of electricity through metals, leaving perhaps only one outstanding unsolved problem, superconductivity.

J. J. Thomson himself had noted that the mass of the electron increased with the speed, the first and the simplest proof of relativity. The incorporation of the relativity idea into the equations for the electron was done brilliantly by Dirac, and this not only reproduced all the known cases for slow-moving electrons, together with a gratuitous 'spin', but also introduced negative energy states predicting the existence of the positron, discovered somewhat later. Prof. Peierls, in conclusion, referred to the present-day difficulties, stating that the electron will not be completely understood until the reason for its comparatively weak charge is known.

Sir George Thomson was welcomed by Dr. V. Z. de Ferranti, president of the Institution of Electrical Engineers, who reminded the audience that Sir George was best known for his discovery of electron diffraction, in which the electron behaves as a wave, and which has had important industrial developments.

Two applications of electrons, their use for the study of the very small, and for the production of very high voltages, were considered by Sir George, in his lecture on the electron in research. Since electrons possess wave properties analogous to light, any optical instrument has an electron analogue. The two most important are the electron microscope, which follows its optical model very closely whether employing electrostatic or magnetic lenses, and the electron diffraction camera, where the electrons are diffracted by the regular arrangement of the atoms in a crystal, similar to light by a ruled grating. Dr. Raether's work on the polishing of rock salt, in which the surface was examined both by electron diffraction and by the electron microscope, was described by Sir George, and slides shown of the results obtained to illustrate the use of electrons for the examination of the very small, and the complementary nature of the two methods.

Nuclear physics requires energies of not less than 100 MeV., so that methods of producing high voltages are becoming increasingly important. Limiting attention to electrons, the Van de Graaff electrostatic generator, the betatron, the synchrotron with its variant the microtron, and the linear accelerator are the more important machines for generating high-speed particles, and these were briefly explained by Sir George, who gave several interesting details of some of the generators now in use or under construction. The high-energy electrons, it was pointed out, are most often used to produce X-rays, of great value industrially for the examination of castings, etc., and medically for direct use in therapy.

The applications of electrons in industry was the subject of the lecture by Dr. Allibone, who followed Sir George, and who was introduced by Dr. P. Good, president-elect of the Institution of Electrical Engineers. Dr. Allibone confined his remarks to the free electrons, that is, electrons separated from the atoms to which they are usually attached. He pointed out that Sir J. J. Thomson in 1895 and 1897 dealt with free electrons, and that J. J. Thomson's modified Crookes tube was the forerunner of the present-day cathode ray tube, which industry has developed and is now producing at the rate of 100,000 a year, rising very shortly to a million a year. Modern developments of cathode ray tubes have concentrated on improving the electron optics, and on increasing the energy, of the electron beam, in order to meet the desire of the engineer to examine electrical transients of very short duration. Dr. Allibone referred to several of the improvements that have been made, and to other applications of the cathode ray tube, in radar and projection television. He next reviewed thermionic emission, and the many different types of thermionic tubes, giving instances of their uses, particularly in induction and dielectric heating and in communication engineering. But J. J. Thomson's observations were not confined to electrons liberated by thermionic emission. In 1899, as Prof. Crowther mentioned earlier, he had measured *e/m* for electrons emitted by photo-electric emission from a zinc plate illuminated by ultra-violet light. Modern technique has now extended the photo-electric effect into the infra-red region, and the photo-electric cell finds its application in thousands of industrial processes. Dr. Allibone singled out for special mention the electron multiplier, the television camera, and the war-time development of infra-red sensitive cells. Finally, he dealt with field emission, that is, electrons made free from a surface by the action of intense external electric fields, a phenomenon which J. J. Thomson never examined himself, but which is important in several branches of vacuum engineering. Dr. Allibone concluded his interesting talk, which he had illustrated by many slides, by showing a portion of the film of Sir J. J. Thomson, which the Institution of Electrical Engineering made some ten years ago, and which represents 'J. J.' in the affectionate manner which endeared him to all.

The public lecture delivered by Sir Clifford Paterson, who has the distinction of being a past president of both the Institute of Physics and of the Institution of Electrical Engineers, was naturally less academic than the four lectures delivered before the learned societies. The audience was entertained by an instructive series of experiments and demonstrations, in which they saw how the scientific worker and the engineer, armed with the knowledge provided by J. J. Thomson that electricity consists of an immense number of minute particles, the electrons, have devised means of liberating these electrons from solids, and then developed and used every kind of free electron agency and device. Forty years of development has resulted in a vast industry, 'electronic engineering', engaged in the production of these numerous electric devices, which have changed and are indeed revolutionizing the life of the community. Two electron liberator devices in particular, the radio valve, utilizing thermionic emission from a filament and controlling the electron stream by means of the other electrodes, and the photo-electric cell, which has a specially sensitized cold surface from which electrons are liberated by the action of light, were described by Sir Clifford. To illustrate the power of the tool that the physicist has put into the hands of the electrical engineer, a most convincing demonstration was given of the conversion of sound from a gramophone record into electrical impulses, then into light waves, back into electrical and mechanical waves to sound once more, with several intermediate stages of amplification. In the latter half of the lecture, electrons in relation to lighting was discussed. The progress made in gaseous discharge tubes for illumination purposes was elegantly demonstrated, as well as the improvement in the ordinary electric lamp. It is interesting to note in this connexion that if fluorescent lamps became universal, a saving of nearly two million tons of coal a year and two large generating stations the size of that at Battersea could be effected.

Although the celebrations were to mark the jubilee of the electron, everyone who listened to the lectures or sees the Exhibition is bound to be impressed by the still great youthfulness and vigour of the electron, for the potentialities of the new science of electronics are attracting to their study and exploitation such an amount of skill and enterprise that what has been accomplished can be regarded only as a beginning of the achievements of the liberated electron.

S. WEINTROUB

INTERNATIONAL STANDARDS AND UNITS OF RADIOACTIVITY

THE first international radium standard was prepared by Mme. Curie in 1911; it consisted of 21·99 mgm. of purest radium chloride. By comparing its radiation with those from other radium sources, the latter could be measured and their radium contents expressed in grams. For the measurement of radon, grams (or cubic centimetres) of this gas are impracticable as units, and it was therefore decided to use as unit of radon the quantity which is in radioactive equilibrium with 1 gm. of radium; it was called a 'curie'. Standards for radon measurements were prepared in the form of solutions of radium salts.

Since the comparison of radioactive sources with the standards always involved measurements of ionization currents, or of the number of disintegrations per unit of time, and as especially the latter figure could be determined with much higher accuracy than the weight of the radium preparation, it became customary to base the curie directly on the number of alpha-particles emitted. According to the best measurements, 1 gm. of radium and, naturally, also the radon in equilibrium with this quantity, emits per second $3 \cdot 7 \times 10^{10}$ alpha-particles; in recent practice, unknown radioactive sources were measured in curies by comparing their particle emission with this figure. Thus the curie became the unit in which the strength not only of members of the radium family, but also of any radioactive source, could be expressed.

This important change in the principle of radioactive measurements and in the definition of the curie was never officially sanctioned, because the International Radium Standard Commission which was responsible for the early conventions on radioactive standards and units has for a long time not been able to function satisfactorily. To remedy this situation, the proposal was made by E. U. Condon and L. F. Curtiss (*Rev. Sci. Instr.*, **17**, 249; 1946) to introduce as a new unit the activity of 10^6 disintegrations per second, and to call it a 'rutherford'.

It is obvious that an international agreement is imperative, whether the 'curie' in its original or in its modified form, or the new unit, the 'rutherford', should be used. The International Congress of Chemistry recently held in London offered to a number of workers in radioactivity from various countries an opportunity to discuss this question among themselves. Under the chairmanship of Prof. F. Joliot-Curie (Paris), on July 19, a meeting was held by Ellen Gleditsch (Oslo), G. de Hevesy (Stockholm), Irene Joliot-Curie (Paris), C. Jacobsen (Copenhagen), W. A. Noyes, jun. (Rochester), F. A. Paneth (Durham) and G. J. Sizoo (Amsterdam); and after an exchange of views they decided to make the following recommendation.

A new committee on radioactive standards and units, comprising mainly representatives of the International Union of Chemistry and of the International Union of Physics, should be formed; but all the surviving members of the old International Radium Standard Commission should be invited to join them. As representatives of the International Union of Chemistry the names of E. Gleditsch, G. de Hevesy, Warren C. Johnson, F. Joliot-Curie, F. A. Paneth and G. T. Seaborg were suggested; as representatives of the International Union of Physics those of L. F. Curtiss, Sir Charles Darwin, R. B. Evans, C. Jacobsen, Irene Joliot-Curie and G. J. Sizoo.

Those present at the meeting were unanimously in favour of preserving the name of 'curie' as the unit of radioactivity, but to define it now officially as the quantity of a radio-element which undergoes $3 \cdot 700 \times 10^{10}$ radioactive transformations per second. The final decision, however, will have to await the recommendations of an international committee on radioactive standards, the formation of which was advocated.

QUANTITATIVE ASPECTS OF FREE RADICAL CHEMISTRY

By Prof. H. W. MELVILLE, F.R.S.

University of Aberdeen

THE Faraday Society held a two-day meeting in Oxford during September 23–25 to discuss "The Labile Molecule", or the quantitative aspects of free radical chemistry. The nature of the discussion seemed commonplace enough, and the tremendous activity in this field of chemistry is almost taken for granted. If we neglect the war years—and that is not quite justified—the subject seems to have grown up in about five scientific years, from a rather tentative qualitative notion to a subject of considerable precision requiring for its practice a wide variety of advanced techniques.

The attempts to unravel the mechanism of chemical reactions, the mechanism of which does not involve ions, is really the story of the development of the kinetics of homogeneous reactions. Many reactions, and especially those involving halogens, are known to involve free atoms as essential intermediates. These are, in fact, the activated 'molecules' in the old Arrhenius sense. But the idea that free organic radicals could function in a similar way, though possible in principle, came at a much later stage. The preparation of simple aliphatic radicals by the thermal decomposition of metallic alkyls, and later of a large number of simple organic molecules, provided the idea that radicals might play a part in the thermal decomposition of molecules the spontaneous decomposition of which was regarded as occurring simply by fission into simpler molecules but not radicals. Similarly, a great deal of work on the photochemical decomposition of compounds like the simpler aliphatic ketones could only be satisfactorily explained if it were assumed that the first step in the reaction consisted in the fission of a carbon – carbon bond with the production of two free radicals. Such experiments, however, gave little quantitative information about the reactivity of the radicals produced, for the simple reason that the radicals mostly recombined, and therefore the velocity of decomposition was fixed by the initial rate of decomposition of the ketone. The kind of information that is now required about the behaviour of radicals is much more comprehensive, for it is a relatively easy matter to find whether radicals are involved in a reaction; and often the chemistry of the reaction is simple enough for the precise nature of the radical to be specified. There are at least four distinct types of radical processes about which quantitative information is required. (*a*) The rate of radical production by thermal activation, by thermal decomposition of relatively unstable substances such as peroxides and azo compounds and by photodecomposition of molecules. (*b*) The interaction of radicals with saturated molecules, in which usually an atom is removed, generating thereby another kind of radical the reactivity of which may differ markedly from that of the original radical. (*c*) The interaction of radicals with unsaturated molecules in which the radical adds on to the double bond, producing in this way a larger radical again of a different activity from that of the original. (*d*) The interaction of radicals with each other or with other radicals present. Such a process is the only way in which the radical is finally removed from the system.

This general list of collision types comprises the essential steps in all radical reactions, no matter whether the overall effect is the oxidation of hydrocarbons, the polymerization of vinyl compounds, the addition of carbon tetrachloride to olefins, or the addition of hydrogen bromide to double bonds between carbon atoms. It is with this more general aspect of free radical chemistry in mind that the discussion took place, and in particular the emphasis was laid on the absolute magnitude of the velocity coefficients of the above-mentioned reactions. This quantitative approach raises at once two matters. First, it is necessary to devise methods of measuring velocity coefficients, which implies a kinetic analysis of reaction mechanism with a degree of unambiguity and precision which is not easily attained. Secondly, the provision of data of this kind gives the theoretical chemist great opportunity to attempt further to correlate reactivity and chemical structure for free radical reactions.

For convenience, the discussion was broken up into the following constituent parts, each of which has contributed much to our understanding of free radical reactions: (*a*) a theoretical part dealing with the calculation of the structure, energies and reactivity of free radicals; (*b*) radical reactions in the gas and liquid phases; (*c*) oxidation reactions; (*d*) polymerization reactions. Although the existence and behaviour of free radicals was first studied in the gas phase, the predominant interest appears to have shifted to the liquid phase, where the variety of effects is naturally much greater. Fortunately, it appears that the complications that might arise in working in a condensed system are not quite so serious as were first imagined.

In spite of a great deal of experimental work, the reactions of gaseous simple hydrocarbons with free radicals derived from them are still somewhat obscure, and much effort is still required before even qualitative data can be reliably obtained. For example, there is only now fairly general agreement about the energy of activation for the $CH_3 + H_2 \rightarrow CH_4 + H$ reaction, namely, between 7 and 9 k.cal., the temperature-independent factor not being particularly small. Besides monoradicals, great interest is attached to the behaviour of diradicals, both in hydrocarbon chemistry and in polymerization reactions. The methylene radical can be produced either by the photodecomposition of keten or by the action of sodium vapour on methylene bromide. In the former case, the CH_2 molecule attacks metallic mirrors with vigour, and it must be presumed that it acts as a diradical and not as a stable molecule CH_2. Yet when produced under the conditions obtaining in a sodium 'flame', the radical does not apparently dimerize to ethylene but undergoes a variety of other reactions. Another very interesting way in which aliphatic free radicals can be formed at low temperatures is by the thermal decomposition of silver methyl and silver ethyl, in the range − 60° to − 20° C. With ethyl radicals both combination and disproportionation occur even at these low temperatures.

Oxidation of hydrocarbons to hydroperoxides is now well recognized to occur by a mechanism involving *R*- and *R*OO-radicals. Even the OH radicals produced by the interaction of Fe^{++} and hydrogen peroxide will provide the necessary stimulus for initiating oxidations of this type. Further, it is now becoming clear that the action of retarders in such oxidations involves the attack of the retarder by the *R*OO— radical. By the use of hydroquinones and similar compounds as retarders, it has been shown there is a quantitative relationship between the logarithm of the velocity coefficient and the oxidation-reduction potential of the hydroquinone–quinone system. In the hydrogen–oxygen reaction, the radical corresponding to RO_2 is HO_2, the existence of which seems essential to the formulation of a satisfactory scheme of reaction. Similarly, a theoretical investigation confirms the stability of this radical, though no direct evidence is as yet forthcoming. Spectroscopic examination of flames provides conclusive proof of the existence of radicals, BrO and CBr being recent additions to the list. The difficulty, as always, is to determine whether such radicals exist under conditions where flame propagation is absent. The CHO radical can be identified in flame, and now its presence has been detected in photodecomposing formaldehyde by exciting it to fluorescence in the ultra-violet region of the spectrum.

The advances that have been made in studying the polymerization of vinyl compounds have provided more information about free radical processes than any other type of reaction. It is now so firmly established that these chain processes occur through the intermediary of free radicals that it almost becomes possible to use polymerization reactions as a suitable tool to study free radical reactions. Here, fortunately, there is no doubt about the general nature of the free radical, for it is either derived by the opening out of the double bond to form a diradical or by the attachment of a separately produced monoradical *R*— to the double bond: $R + CH_2 = CHX \rightarrow R.CH_2.CHX$. One very common method of producing *R*— radicals is from the decomposition of peroxides of the type $(R.COO)_2$, the radical *R*COO being first formed and carbon dioxide eliminated before *R*COO attacks the double bond. Other radical-producing substances are badly needed, and now it is reported that N-nitrosoacylarylamines will function in a similar fashion. For example, N-nitroso acetanilide will break up with the formation of a phenyl and acetate radical and the elimination of a molecule of nitrogen. While it is of great importance to measure the rate of production of radicals in polymerization, the most important step is the interaction of the radical derived from the monomer, namely, $R - + CH_2 - CHX$ with another monomer molecule to form a still larger radical—the all-important growth-step.

In order to compute the velocity coefficient from the rate at which monomer disappears, it is necessary to know the stationary concentration of the free radicals. Fortunately, this can now be done, since we know the rate of production of radicals and the time required for the concentration to fall to half its value when the source of activation is removed, either by the use of intermittent radiation when the life is short, or by direct observation of the decay of the rate of polymerization when the life is long. Unfortunately, the results are confined to vinyl acetate, methyl methacrylate and styrene at present; hence it is a little too early to see how structure affects reactivity. In the meantime, information has been obtained in a somewhat less direct manner. By studying the copolymerization of two monomers A and B, and analysing the composition of the copolymer formed during the reaction, starting with known concentrations of A and of B, it is possible to calculate the value of two factors, namely, the ratio of the rates of reaction of A and of B with a B-radical, and the ratio of the rates of reaction of A and of B with an A-radical. Therefore, A may be kept fixed and the nature of B altered by changing the nature of the substituent X of the vinyl compound $CH_2 = CHX$. In this way it is possible to get a whole series of monomer reactivity ratios which give relative values for the growth steps in polymerization.

This material has provided the data for tentative theories of reactivity. As a first approximation, it may be supposed that there can be ascribed a potential reactivity of the free radical and also of the monomer which is going to be attacked. It has been suggested that the magnitude of the electric change on the group X will play a predominant part in effecting radical – molecule interaction, and there is some evidence to support almost a purely electrostatic approach to the theory. On the other hand, there is another school of thought which argues in rather a different way; basing relative reactivity on the relative values of the resonance energy of the radical–monomer system before, during and after interaction. Qualitatively, it is possible to go some way with such theories, and most important of all, to incorporate radical – monomer reactivity in the more general theory of the effect of the character of substituents in the reactivity of neighbouring groups. There is, however, a long way to go before any attempt is made to compute the absolute value of velocity coefficients. Indeed, it is only fair to say that in nearly all cases the temperature-independent and temperature-dependent factors have not yet been separately determined, and the theory is wholly based on the values of velocity coefficients determined at one temperature.

When polymerization is carried out in solution, it often happens that the polymer radicals attack the solvent molecule, removing an atom, regenerating another radical which reacts with further molecules of monomer. Thus the kinetic chain is continued, but the continuity of the polymer chain is broken in this so-called transfer reaction. By observing the influence of solvent on the degree of polymerization of the polymer, it is possible to compare the relative activities of the radical attacking the monomer on one hand and the solvent on the other. Absolute values of the radical – solvent interaction can then at once be obtained if the growth coefficient is known. Polymer reactions thereby provide a very convenient and sensitive means of studying a great variety of reactions. For example, when the solvent is hydrocarbon the dominant factor that seems to govern the reactivity is the bond-strength of the weakest C—H bond. Further, if the hydrocarbon radical so produced is stabilized by possessing a large resonance energy, it may not react with the monomer, and so the kinetic chain comes to a stop. The solvent then acts as a retarder for polymerization and the molecular weight of the polymer is cut down. There is therefore little formal difference between transfer and retardation.

Degradation of vinyl polymers also presents interesting information on radical reactivity. In some cases it would appear that the mechanism of degradation is really like polymerization in reverse. If it should happen that thermal fission of a polymer occurs into two free radicals—a relatively difficult process because C—C bonds have to be broken—these radicals are rather unstable in the sense that not much energy, for example, 16 k.cal., is required to remove monomer units. Such radicals are therefore very easily removed from the system. Like the building up of polymers by chain processes, this degradation can likewise be materially diminished by adding substances that will stabilize the radicals and prevent further degradation.

PLANT TUMOURS AND ANIMAL CANCER

By R. S. de ROPP
New York Botanical Garden

THE discovery by Smith and Townsend[1] that crown-gall disease of plants was caused by a bacterium (*Phytomonas tumefaciens*) aroused considerable interest among students of cancer. The view that animal cancer was of bacterial origin was vigorously put forward by Smith, who published several papers emphasizing the resemblance of plant galls produced by *Ph. tumefaciens* and to cancerous neoplasms. He distinguished several different types of plant tumours which he compared to sarcomas, carcinomas and teratomas. Secondary tumours which sometimes formed on infected plants at points remote from the original tumours were compared by Smith to the metastases observed in animal cancer. Smith was convinced that the galls produced by *Ph. tumefaciens* always contained the bacteria within their cells. As investigators of animal cancer failed to isolate any bacterium which could be definitely associated with the formation of cancer, interest in Smith's views tended to decrease.

In 1918 a paper was published by C. O. Jensen[2] which gave the first indications that tumours initiated by *Ph. tumefaciens* might continue to grow as tumours in the absence of the bacteria. Jensen worked with mangolds and sugar beets and succeeded in grafting tumour tissue from these plants on to normal roots. Many of these grafts took, and the tumour tissue continued to grow as a tumour. From all such transplanted tumours Jensen found that the original crown-gall bacteria had disappeared.

The importance of these findings was overlooked until Braun and White[3] began their studies on the secondary tumours which develop on certain plants after inoculation with *Ph. tumefaciens*. These secondary tumours were first described by Smith, who considered them to result from strands of tumour tissue which, carrying the bacteria within their cells, grew through the stems of infected plants and produced secondary or metastatic tumours. It was shown by Braun and White that such secondary tumours on sunflower are usually free from bacteria. By the application of tissue culture methods to this material, these workers were able to demonstrate that tissues removed from secondary tumours on *Helianthus annuus* will grow readily on a simple medium containing mineral nutrients, 2 per cent glucose, thiamine and glycine. White and Braun[4] also showed that normal sunflower tissue and tissue removed from tumours induced with indole-oxaloacetic acid grew much more slowly in culture and tended to differentiate roots and to form chlorophyll, which did not occur in the tumour tissue. The tumour tissue continued to proliferate abnormally when grafted *in vivo* on to stems of *Helianthus annuus* or *Helianthus tuberosus*. Bacteria-free tumour tissue capable of unlimited growth *in vitro* was also isolated from *Vinca rosea* (periwinkle) by White[5] and from primary, as opposed to secondary, tumours on sunflower by de Ropp[6].

Early in the study of crown-gall it was realized that galls would form only when bacteria encountered wounded tissue. Hildebrandt[7] showed that a single organism was sufficient to produce a gall when introduced into a needle puncture wound; but crown-gall organisms introduced directly into living cells of tomato stems "failed to induce gall formation and ordinarily failed to survive inside the cells, indicating that the living cell interior is an unfavorable medium for these bacteria". Afterwards it was shown by Braun[8] that wounded plant tissue may be rendered tumorous by the crown-gall organism in as little as 36–48 hours. He obtained this information by treating wounded stems of *Vinca rosea* with crown-gall bacteria and afterwards freeing them from the bacteria by heat. Tumour tissue developed at the site of these wounds even though the bacteria causing tumefaction had been eliminated. Following earlier work of Riker[9], Braun[10] also showed that tumour formation in wounded periwinkle tissue was inhibited at 32° C. even though virulent crown-gall organisms were present in the wounds. Some further light was thrown on the mechanism of tumour induction by work of Braun and Laskaris[11], who showed that tomato plants inoculated with a strain of *Ph. tumefaciens* which had lost its capacity to induce tumours would respond with tumour formation if treated with indole acetic acid. They concluded that a tumefacient factor and a growth hormone were both involved in tumour formation.

The sensitivity to hormones of bacteria-free crown-gall tumour tissue as compared with normal tissue was studied by de Ropp[12], who showed that, although normal tissue would respond with root formation to one part per 100,000,000 of indole acetic acid, tumour tissue was not affected by this substance. He attributed this lack of response to an excess of growth hormone present in the tumour tissue. The presence of an excess of growth hormone in plant tumour tissue was also indicated by studies of Brown[13], Riker[14], and others, who showed that plants infected with crown-gall frequently produced adventitious roots from normal plant tissues in the region of the gall. Attempts by Riker[14] to demonstrate differences in auxin concentration between normal and tumour tissue by means of the *Avena* coleoptile test were not successful.

Experiments on the interaction of normal and tumour tissue were performed by de Ropp[15], using the method of *in vitro* grafts. It was shown that 'induced tumours' frequently developed in these grafts which appeared to arise not from the tumour tissue but from the normal stem tissue to which it had been grafted. The induced tumours differed from the inducing tumour tissue in morphological characteristics but proved capable of inducing tumours when grafted to normal tissue. To account for the formation of these induced tumours, a tumefacient agent was postulated having the property of a virus or a self-perpetuating cytoplasmic entity such as has been suggested by Darlington and Haddow. If a virus is responsible for the formation of induced tumours, it is probably of the type transmissible only by grafting, as extracts of tumour tissue are without effect on normal tissue (White and Braun[4]; de Ropp[16]). The existence of such a bacteria-borne tumefacient factor has still not been conclusively demonstrated.

A comparative cytological study of crown-gall tissue and various forms of cancer tissue was made by Levine[17], who observed giant cells in the gall tissue, the nuclei of which were sometimes in the tetraploid or octoploid condition.

Two other forms of plant tumour are of interest to students of cancer, namely, the virus wound tumour of Black[18], and the *Nicotiana* hybrid tumour of Kostoff[19]. Susceptible plants can be affected with the wound tumour virus either through the agency of agallian leaf hoppers or by being grafted to infected plants. Infection is systemic and symptoms include enlargement of the veins as well as the formation of tumours on roots and stems in many species of infected plants. Most of these tumours appear to arise at points where root or stem has been wounded. Black[20] showed that the tumour tissue from sorrel could be cultured for as long as twenty months on an artificial medium without the production of roots, stems or leaves. On being grafted back to healthy plants, tissues from these cultures induced a systemic infection in the stocks, showing that the virus was still present. Such a tumour-producing virus has obvious resemblances to entities such as the Rous sarcoma virus or the Bittner milk factor.

The tumours which arise on hybrids of *Nicotiana Langsdorfii* and *N. glauca* were described by Kostoff and later studied by Whitaker[21]. Such tumours develop only in hybrids in which *N. Langsdorfii* is used as the pollen parent. The tumour tissue was cultured *in vitro* by White[22], who showed that it would continue to grow as a tumour when grafted back on to normal plants. He showed also that this tumour tissue was capable of differentiating organs *in vitro*, in which respect it differs from crown-gall tissue and virus wound-tumour tissue.

Clearly, the three forms of plant tumours here described have certain properties in common with those neoplasms in animals which are collectively referred to as cancers. The resemblance is closest in bacteria-free crown-gall tissue and Black's virus-tumour tissue. *Nicotiana* hybrid tissue seems more nearly normal in its behaviour, having the capacity to differentiate organs which the other tumour tissues appear to have lost. It is interesting to note that gall formation by *Ph. tumefaciens* and Black's virus seem always to be associated with wounding, suggesting that a hormone mechanism is involved. In *Nicotiana* hybrid tumours the abnormal growth results, according to Whitaker, from a cytoplasmic disturbance occasioned by the introduction of the chromosome complement of *N. Langsdorfii* into the cytoplasm of *N. glauca*. Thus, the work on plant tumours has brought to light three factors—virus, hormone and genetic—which may act singly or in combination to produce pathological growth. This trio of etiological agents is already familiar to students of animal cancer.

NEWS and VIEWS

Royal Society: Anniversary Meeting

In the course of his anniversary address, delivered on December 1, to the Royal Society, the president, Sir Robert Robinson, referred to the fact that, as "a privileged body", the Society, represented by the president, vice-presidents, and officers, attended at Buckingham Palace to present an address on the occasion of the marriage of Princess Elizabeth to Lieut. Philip Mountbatten; the King replied, referring to the intimate association for so many years between the Royal Society and the Crown.

Sir Robert also read the following telegram, sent by the Council of the Royal Society to Sir Charles Sherrington on the occasion of his ninetieth birthday on November 27:

"The Royal Society sends you its greetings and good wishes for your birthday. We think of our former President with especial pride and affection—we are proud of your scientific achievement, of the fresh light you have thrown on the hidden dealings of the nervous system, of the many pupils you have inspired and of the originality and distinction which has informed your scientific writing. We are proud of the philosopher who has first learnt the wisdom of the body and of the poet who can touch the springs of the mind. But on this birthday we think not so much of the great scientist as of the well-loved friend of many years who has won universal esteem by his kindness and generosity and by the courage and purpose of his life. You have set us an example for which we thank you, and we wish you all the happiness which you have so well deserved."

Referring to scientific events of the past year, Sir Robert said the most interesting development in the relations between science and administration during the past year was the formation of the Defence Research Policy Committee and the Advisory Council on Scientific Policy. The two bodies are intended to provide for scientific consultation at the highest level in government. It has been feared, however, that this may lead to infringement of the freedom of research by some form of planning or control. Sir Robert thinks that, apart from what he termed "the subtle effects of selective encouragement", there is little danger on that score; for he feels sure the present Government realizes the importance of untrammelled scientific research and its free development. It has also been objected that the Royal Society is no longer, as in the past, to have direct contact and collaboration with ministers and Government Departments. Sir Robert said in comment on this point that the Royal Society has surrendered none of its power to take the initiative or its traditional privilege of access to authority. The new developments have been the inevitable outcome of the enormous extension of Government interest in scientific work of all kinds, making the creation of a permanent liaison organisation with full-time staff a necessity. The Royal Society took the initiative during the past year in an investigation of the delays occurring in the publication of scientific papers. In the case of the Society's own publications, the time between the receipt of a paper and its publication is now about twice that occurring in 1938. Many scientific societies are probably in worse case. A major cause of this delay appears to be a shortage of skilled compositors; the Minister of Labour and National Service has intervened in the matter and improvement is hoped for. Sir Robert also stated that discussions for improved accommodation for scientific societies had continued. No agreed scheme of co-operation was available, so a committee has been formed to explore the problem in detail and to prepare alternative plans. Sir Robert's scientific theme was "An Essay in Correlation arising from Alkaloid Chemistry"; it is hoped to print this shortly, and also the remarks made during the presentation of the medals for 1947.

Dr. D. C. Martin, formerly of the Chemical Society, took up the appointment of assistant secretary of the Royal Society on January 1, 1947.

Officers for 1948

At the anniversary meeting of the Royal Society held on December 1, the following were elected as officers and council for the ensuing year: *President*, Sir Robert Robinson; *Treasurer*, Sir Thomas Merton; *Secretaries*, Sir Alfred Egerton and Sir Edward Salisbury; *Foreign Secretary*, Prof. E. D. Adrian; *Other Members of Council*, Prof. J. D. Bernal, Prof. W. Brown, Prof. S. Chapman, Prof. A. C. Chibnall, Prof. C. A. Lovatt Evans, Prof. W. E. Garner, Prof. A. C. Hardy, Sir Norman Haworth, Prof. H. D. Kay, Dr. C. H. Kellaway, Prof. M. L. E. Oliphant, Dr. C. F. A. Pantin, Prof. H. H. Read, Dr. A. E. Trueman, Mr. B. N. Wallis and Dr. J. H. C. Whitehead.

Robert Liston (1794–1847)

ROBERT LISTON, who died in his prime of an aortic aneurysm on December 7, 1847, is chiefly remembered as the first surgeon in Europe to operate under ether anæsthesia. He remarked at the time: "This Yankee dodge beats mesmerism hollow". He was not a good writer or speaker, and he contributed little to the science of surgery, but he was unsurpassed as a lightning and dexterous operator, whose methods of crushing stone and amputating thighs were the envy and despair of other surgeons. Educated at the University of Edinburgh, he became assistant to John Barclay, the anatomist. In London he worked under the two Blizards and attended Abernethy's lectures. Quarrelling with the authorities, he was expelled from the Edinburgh Royal Infirmary, but was reinstated as surgeon five years later. In 1834 he was elected surgeon to the newly founded hospital attached to the University of London. Six feet two inches in height, Liston was a man of fabulous strength, whose brusque voice was known to strike terror in the hearts of students and patients. His publications include "The Elements of Surgery", 1831–32, and "Practical Surgery". 1837. Liston is eponymously commemorated through 'Liston's long splint', which remained popular well into this century, and through 'Liston's bone-forceps', which are still in common use.

Science in Post-Primary Education

IT is encouraging to see that the Association of Women Science Teachers is fulfilling its aim of producing a series of reports on science in post-primary education. Whereas Parts 1 and 2 of this series dealt more with the principles of this education, their application to grammar school pupils of 11–18 years, and reference to subsequent training in universities and colleges, the third part of the report just published has been written in response to requests for advice on science syllabuses to those planning courses in the secondary modern schools (Science in Post-Primary Education. Third Part of the Report of a Sub-Committee of the Association of Women Science Teachers. Work in Secondary Modern Schools. John Murray, London). Recognizing that a suitably planned science course should be part of every child's work at the secondary stage, the Association of Women Science Teachers now presents specimen syllabuses for the age group 11–13 years for use in schools working under different conditions. The syllabuses are drawn up in various ways with the intention of avoiding uniformity and of offering suggestions for different methods of approach; the basic content of each has been tested by teachers in secondary modern schools. They are suitable for: a town school with laboratory and children of average ability; a similar school with children of below-average ability; a rural school with no laboratory and children of average ability; a similar school with children of below-average ability. A perusal of these syllabuses will show that the compilers recognize that the interests of the children should form the starting point for the study of scientific problems and that the study of plenty of examples and applications should come before principles are given, many difficulties in the past having arisen by the imposition of deductive thinking on those for whom it is unsuitable. It is hoped, therefore, that those teachers introducing the study of science as elementary general science into the new secondary schools will find these syllabuses useful. The compilation of syllabuses for the age group 13–15 years is contemplated, should there be a demand for them.

Physical Society of Württemberg and Baden

THE Physical Society of Württemberg and Baden recently held its first post-war meeting in Stuttgart; the meeting was convened by Prof. Erich Regener, known for his pioneer work on cosmic rays. The meeting, which lasted two days and was attended by some two hundred members, approved a significant alteration in the Society's statutes. Instead of stressing as before the purely scientific purposes of the Society, paragraph 2 now runs as follows: "The fact that the knowledge gained in physics increasingly influences the mental attitude of mankind and penetrates into all domains of human activity, imposes upon the Physical Society the obligation of keeping alive in scientific workers a sense of sharing the responsibility in the shaping of human life. The Society shall stand for the freedom, the truth and the dignity of science." In a report explaining this change, Prof. Regener points out how the trend towards de-personalization of the whole world-picture even manifested itself in the description of results (compare the frequent use of such phrases as "it has been observed", "computation shows" . . .), and how physicists often disregarded all practical applications of their science, except as a means to make better experiments. After the experience of recent years (atom bomb, etc.), the physicist can no longer be 'disinterested' in the consequences of his work without injuring both his science and himself. "Physics—and the attitude of physicists—stands to-day at the focus of public interest. The only possible attitude for us is to declare as valuable nothing but what serves the welfare of mankind, and to discard anything opposed to it."

Over-population as a World Problem

SIR JOHN MEGAW's experiences in India have impressed on his mind the need for a sustained effort to replace the natural checks on population, such as disease, famine and war, by arrangements that will involve less suffering and less inefficiency of the survivors (Occasional Papers, No. 1. British Social Hygiene Council, London. 6*d*.). He is deeply appreciative of Malthus, whom he defends against some current misjudgments. He shows that the efforts to raise standards of living above misery in Porto Rico, and in India, have largely failed because the birth-rate, or rather the survival-rate of infants, in several cases has gone up. In Porto Rico production of sugar in 1928 was nine times that of 1899, and in the same period literacy went up from 15 to 60 per cent of the population. Yet, under-feeding and general misery remain characteristic, with a birth-rate still of 40 per thousand but a death-rate reduced from 27·1 to about 20·6. The population in 1940 was nearly 1,900,000 and is now more than 2,000,000 on 3,423 square miles. The future of such a community is full of problems unless the birth-rate declines. India's increase of nearly 5,000,000 a year is even more formidable, because the problem is on such a large scale. The bibliography at the end of the pamphlet is not a very good one. Prof. A. V. Hill contributes a useful preface to the pamphlet and hopes that education carried far beyond mere literacy may help.

Indian Association for the Cultivation of Science

The annual report of the Indian Association for the Cultivation of Science, Calcutta, for the year 1946 includes the report of the managing committee, to which are appended the accounts, lists of papers published in 1946, of books added to the library and periodicals received through exchange, and of office bearers and members of the Committee of Management and the report of the Mahendra Lal Sircar professor on the scientific work of the Association. M. N. Datta's further study of the sharp type of extra spots in the extra reflexions of X-rays from phloroglucinol dihydrate has given strong support to the theory of the origin of these two types of extra reflexions advanced in earlier reports, and studies of the effect of high temperature on the phenomenon yield further support to the view that the extra spots do not originate from thermal oscillations or crystal defects. R. K. Sen continued his studies on the extra reflexions due to planar derangement waves in benzil and has also studied the diffuse extra spots of thermal origin with pyrene. B. S. Basak has extended intensity measurements of the reflexions from benzil to a large number of planes, including even weak planes, to improve upon the Fourier projections of this crystal. With A. K. Raichowdhury, he has also set up a suitable X-ray tube for studies on the structure and phase diagrams of alloys of beryllium and aluminium, and beryllium and copper. B. K. Banerjee has continued X-ray investigations of glass systems, including dispersions of platinum in Lindemann glass and of cobalt, nickel, copper and chromium oxides in borax glass. X-ray studies of Indian coal have been made by N. N. Gupta, and A. K. Datta's studies of the electrical conductivities of well-developed single crystals of molybdenite indicate that the conductivity at higher temperatures is predominantly electronic. The absorption and fluorescent spectra of anthracene, perylene, phenanthrene, naphthacene and pyrene in different solvents have been investigated by S. G. Ganguly in an attempt to determine the cause of the variations in spectral distribution of the fluorescent light with the solvent used.

International Society for Cell Biology

Before the War, international congresses on experimental cytology were organised by the International Society for Experimental Cytology. The International Cytological Congress held at Stockholm during July last was held under the auspices of a truncated committee of the International Society. At this Congress the old Society was dissolved, and a new Society, the Society for Cell Biology, was founded. The new Society will be responsible for future international cytological congresses. It is a member of the International Union of Biological Sciences. At Stockholm the following officers and committee were elected: *President*, Prof. J. Runnström (Sweden); *Vice-Presidents*, Dr. E. Fauré-Fremiet (France), Prof. E. Newton Harvey (United States), and Dr. G. Levi (Italy); *Secretary and Treasurer*, Dr. J. F. Danielli (Great Britain); *Committee*, Prof. T. Caspersson (Sweden), Dr. Honor B. Fell (Great Britain), Prof. A. Frey-Wyssling (Switzerland), Prof. G. C. Heringa (Holland), Prof. H. Okkels (Denmark) and Prof. Paul Weiss (United States). Many of these officers and committee members held office in the old International Society for Experimental Cytology, and Prof. Okkels was its secretary. An invitation has been received asking the new Society to hold the next Cytological Congress in the United States.

Election to membership of the new Society for Cell Biology will normally be based on original contributions to knowledge in experimental cytology and experimental histology, and related fields. One hundred foundation members were invited to participate in the formation of the new Society. These were mainly chosen from those present at the Stockholm Congress, but included a few who had given distinguished assistance to the old Society. Applications for membership of the Society for Cell Biology will be welcomed. They may be addressed to Dr. J. F. Danielli, Royal Cancer Hospital, London, S.W.3, England, or may be sent in the first instance to any officer or committee-member of the Society. Applications should normally be accompanied by a list of references to original contributions to knowledge.

International Commission on Large Dams

The first Congress on Large Dams was held in Stockholm in 1933, concurrently with the Scandinavian sectional meeting of the World Power Conference; the second was held in Washington in 1936, concurrently with the third World Power Conference. The third Congress on Large Dams will be held in Sweden next year. It will not be associated with a meeting of the parent organisation, since no meeting of the World Power Conference is planned for 1948. The organisation of British participation in this Congress is being undertaken by the British Committee on Large Dams, which is a sub-committee of the British National Committee of the World Power Conference. The general lines of the Congress will be as follows: (*a*) critical exposition of the measurement of uplift pressures and stresses arising therefrom; (*b*) research methods and instruments for the measurement of stresses and deformation in earth and concrete dams; (*c*) recent precautions to avoid the formation of pipings; (*d*) experiences arising from the testing and the actual use of special cements for large dams.

The Congress will open in the Concert Hall (Konserthuset) at Stockholm on June 10. The next two days are to be devoted to meetings, which will also be held in the Concert Hall. These meetings will be followed by a five-day study tour to a number of dams and hydro-electric power plants, and to one of Sweden's large industries. The tour includes a visit to the waterfall at Harsprånget (Hare's Leap), situated north of the Arctic Circle and in process of development (the capacity of the power station there is to be 260,000 kW.). The study tour will close with meetings in Trollhättan. Preliminary notification of intending participation must be forwarded to the Swedish Committee on Large Dams, through the Secretary, British National Committee of the World Power Conference, 201–2 Grand Buildings, Trafalgar Square, London, W.C.2, not later than December 31, 1947.

The Medical Bookman and Historian

The *Medical Historian*, believed to be the first periodical in Britain to deal solely with the history of medicine, was not able in present circumstances to appear as an independent journal. It has therefore been linked with the *Medical Bookman*, and the first issue of the new combined journal, *The Medical Bookman and Historian* (Harvey and Blythe, Ltd., 6 Hanover Square, W.1. Monthly, 2*s*.), has been published. The policy of the *Medical Historian* will be to link the history of medicine with its current practice and to try to elucidate current problems in the light of past experience and past errors. Everyone who is interested in the history of medicine will wish this new journal well and will hope that it will, before long, be able to stand by itself. Meanwhile, its fusion with the *Medical Bookman* is complete. The reader of the combined journal will, in fact, scarcely know which of the contributions belong to either partner in this interesting marriage. Eleven of the fifteen items in the list of contents of the November issue (Vol. 1, No. 11) are reviews of books, the other five being original articles; interesting as the kind of book review here printed certainly is, some readers may prefer to see by a glance at the list of contents which are the original articles and which the book reviews. Three of the articles in this issue are the first articles of a series, namely, "Bypaths in Medical Bibliography", by W. J. Bishop, librarian of the Wellcome Historical Medical Museum, "British Historians of Medicine", by F. N. L. Poynter and W. J. Bishop, and "Rise, Fall and Revivals of Hospitals", by Prof. J. A. Nixon. The other article is by the editor of the *Medical Historian*, W. R. Bett, on "Some Thyroid Pioneers". A notice on the front cover of the journal briefly reports the inaugural meeting of the new Medical Sub-section of the Library Association, which fulfils a suggestion made by Sir William Osler in 1909. The honorary secretary of this sub-section is W. J. Bishop, The Wellcome Historical Medical Museum, 26 Portman Square, London, W.1. An exchange system for duplicate or unwanted books and journals, lists of periodicals and rare books, inter-library loans and other services are contemplated. This is a development which everyone engaged in biological work will heartily welcome.

Sun-Bathing by Birds

RECORDS compiled by John Gibb (*Brit. Birds*, **50**, No. 6; June 1947) show that sun-bathing is a regular habit among passerine and predatory birds. The attitudes adopted show an obvious similarity between different species, whether the bird is facing into or away from the sun. This is typically the fluffing out of the body feathers, opening of the wings and fanning the tail. The odd postures at times may usually be attributed to the bird inclining its body towards the oblique rays of the sun. Juvenile birds are particularly prone to sun-bathing. The suggested part that sun-bathing may play in the process of moult is less clearly indicated, although the dates of records show a tendency to concentrate at times of moult.

Botanical Expedition to Nigeria

A SMALL botanical expedition, under the leadership of Dr. P. W. Richards (Botany School, Cambridge), left England on November 15 for Nigeria. The party includes Dr. G. C. Evans (Botany School, Cambridge) and Dr. E. W. Jones and Mr. J. P. M. Brenan (Imperial Forestry Institute, Oxford), and will continue work in the field until the beginning of April 1948. The chief object of the expedition is to investigate the process of natural regeneration in the evergreen tropical forest, with special reference to Aubréville's 'Mosaic Theory'. It is expected that the greater part of the work will be carried out in the forest reserves of Benin Province; but if circumstances permit, some members of the party will visit the Cameroons and make an ecological study of the little-known montane forests. The expedition has the financial support of the Royal Society and of the Colonial Research Fund.

Ministry of Agriculture and Fisheries: Appointments

THE following appointments have been announced by the Ministry of Agriculture and Fisheries: Prof. J. A. Scott Watson, chief education and advisory officer to the Ministry, formerly Sibthorpian professor of rural economy, University of Oxford, to be chief scientific and agricultural adviser to the Ministry and director-general of the National Agricultural Advisory Service, in succession to Sir William Gavin, who retires on December 31; Mr. Robert Rae, an under-secretary in the Ministry, formerly professor of agriculture in the University of Reading, to be director of the National Agricultural Advisory Service; Mr. F. Grant, principal assistant secretary in the Ministry, to be an under-secretary; Mr. H. G. Lambert, a principal in the Ministry, to take charge of a new branch to organise the special campaign for grassland development recently announced by the Minister as part of the new agricultural expansion programme, the technical officer in charge of which is Mr. W. H. Hay.

Announcements

WE regret to announce that Prof. G. H. Hardy, emeritus professor of pure mathematics in the University of Cambridge, died on December 1; on that day he should have received the Copley Medal of the Royal Society, the award of which to him was announced a short time ago.

THE Lord President of the Council has appointed Sir Frank Engledow, Draper's professor of agriculture in the University of Cambridge, to be chairman of the Food Investigation Board, Department of Scientific and Industrial Research, in succession to the late Sir Joseph Barcroft.

MR. E. A. EVANS, chief chemist to the Wakefield Group of companies since 1915, has been nominated president designate of the Institute of Petroleum for the session 1948–49. Mr. Evans has been chairman of the Motor Industry Research Association since its inception in March 1946; and was chairman of its predecessor—the Automobile Research Committee—during 1944 and 1945. In 1942–43 he was awarded the Crompton Medal of the Institution of Automobile Engineers for his paper on "Extreme-Pressure Lubrication".

THE British Social Hygiene Council is arranging a conference on "Biology in Education", to be held at University College, London, on December 30. Speakers include Prof. J. Z. Young, Mrs. F. M. Holt and Mr. W. L. Sumner. Further information can be obtained from the Secretary, British Social Hygiene Council, Tavistock House North, Tavistock Square, London, W.C.1.

AN Italian Association for the Progress of Zootechny has been established at Milan, under the chairmanship of Prof. T. Bonadonna, of the University of Milan and director of the Lazzaro Spallanzani Experimental Institute for Artificial Insemination.

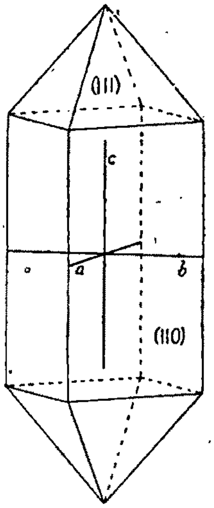
THE report of the Archæological Survey of the Union of South Africa for the period April 1940–March 1946 has appeared (Pretoria: Gov. Printer). Both in quaternary geological studies and in work on prehistoric art, there has been much activity. Dr. van Riet Lowe has had Prof. H. Breuil with him for much of the period under review, and a number of papers and other publications have been issued.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications

Crystal Structure of Human Carboxyhæmoglobin

Mrs. H. M. Jope kindly provided us with crystals of human carboxyhæmoglobin which she had prepared at the Department of Clinical Biochemistry, Oxford. The crystals had been grown by dialysis against 3·5 *M* ammonium sulphate solution at 0° C. and proved to be stable in 3·8 *M* ammonium sulphate solution at room temperature. They were bipyramidal prisms of almost square cross-section (see diagram); sometimes they also grew as octahedra. Birefringence was feeble compared with other protein crystals, and dichroism not detectable.



Oscillation photographs about the three principal axes showed that the crystals were orthorhombic and belonged to the space-group $P\,2_12_12_1$. The unit cell dimensions of the wet crystals are $a=85 \cdot 2$ ($\pm 0 \cdot 2$) A., $b=77 \cdot 0$ ($\pm 0 \cdot 2$) A., and $c=86 \cdot 0$ ($\pm 0 \cdot 5$) A. On drying the crystals, the cell dimensions shrink to $a=70 \cdot 4$ A., $b=73 \cdot 3$ A., and $c=77 \cdot 0$ A. (all ± 1 A.). The crystals contain four hæmoglobin molecules per unit cell. The molecular weight of the protein could not be determined directly, because the salt content of the dried crystals made measurements of the density and water content impossible. However, the close similarity between the unit cell volumes of dried oxyhæmoglobin of horse (393,000 $A.^3$)[1] and of human carboxyhæmoglobin (396,000 $A.^3$) indicates that the molecular weight of human hæmoglobin is very close to that of horse, which is known to be 66,700. The hydration of the protein in neutralized ammonium sulphate solution was determined by the method of Adair and Adair[2] and found to amount to 0·26 gm. H_2O/gm. protein.

The diffraction pattern of the wet crystals consists of sharp reflexions which extend to spacings of the order of 2·5 A., as in all wet protein crystals so far examined. In the dried crystals sharp reflexions fade out beyond spacings of about 7 A. The most interesting features of the diffraction pattern are to be found among the low-order reflexions; we know that in protein crystals these reflexions tend to be influenced by the packing of the molecules rather than their internal structure, and hence they are sometimes capable of providing a clue to the arrangement of the molecules in the unit cell. In human carboxyhæmoglobin, low-order reflexions tend to be either faint or absent unless $h+k$, $h+l$ and $k+l$ are all even; this tendency is most marked among the $h0l$ reflexions and can also be seen to a certain extent among the $hk0$'s and $0kl$'s. It is limited to reflexions with spacings greater than 30 A. This distribution of intensities indicates that the hæmoglobin molecules lie approximately at the corners and face-centres of the unit cell, an arrangement which is compatible with the space-group symmetry; for if one molecule is placed at $x=y=z=0$, the other three molecules in the unit cell would have to lie at the centres of the three faces. Since the edges of the unit cell have almost equal lengths, this brings the molecules very close to the positions of cubic close packing, an arrangement which is all the more likely in view of the octahedral habit of the crystals. It follows that the molecules themselves must be practically isodiametric.

The low optical anisotropy of the crystals indicates that the relative orientation of the four molecules in the unit cell is such as to lead to mutual compensation of the intrinsic molecular anisotropies. This was confirmed by the results of Patterson projections which were prepared along the three principal axes for both the wet and air-dried states of the crystals. These projections showed far more complex peak systems than, for example, horse methæmoglobin[3] or insulin[4], and attempts to find structural features which could be compared with those of other proteins were fruitless on account of the bewildering mass of similar vector peaks occurring in all projections. As in all protein crystals so far examined, there are concentrations of peaks in the region of 10 A.; but this fact by itself does not provide any useful clues regarding the structure of the molecule. It is difficult even in crystals which contain only one protein molecule per lattice point, to derive conclusive information about the intra-molecular structure from the X-ray data. If several molecules are present, and if each of them, moreover, is oriented differently with respect to the crystal axes, as in human carboxyhæmoglobin, the problem soon reaches a prohibitive order of complexity. The chances, therefore, that further analysis of the present structure would lead to fruitful results must be considered remote.

Our crystals were identical in habit with those described by Drabkin and classified by him as tetragonal[5]. Without further data it will be difficult to decide whether Drabkin's crystals represent a different polymorphous modification of the same protein, or whether possibly Drabkin was misled by their pseudo-tetragonal character and his crystals are actually identical with our orthorhombic ones.

Of other derivatives of human hæmoglobin which were examined, oxyhæmoglobin was found to be isomorphous with carboxyhæmoglobin. Methæmoglobin crystallizes in tetrahedra which are probably isomorphous with the octahedral carboxyhæmoglobin crystals examined here, one half of the octahedral faces being undeveloped. Reduced hæmoglobin, on the other hand, crystallizes both as strongly birefringent plates and as bipyramidal prisms the symmetry of which has yet to be found. Finally, it may be worth mentioning that the structure of the carboxyhæmoglobin crystals was the same no matter whether they were crystallized from ammonium sulphate or potassium phosphate solution.

We are very grateful to Mrs. H. M. Jope for having made this investigation possible by providing us with beautifully large, well-developed crystals.

Metabolism of Synthetic Œstrogens in Man

It has long been the practice in carrying out phenol metabolism experiments in animals to measure the increase in ethereal sulphate excretion above the normal average to give an indication of the extent to which the phenol in question is being excreted by sulphate formation. Similarly, a rise in conjugated glucuronic acid excretion above the normal average is taken as proof that the material is being 'detoxicated' by glucuronide formation. In many cases it has been possible to obtain figures by this method upon which rough quantitative metabolic data could be based.

However, in view of the large natural daily variation of both ethereal sulphate and glucuronide excretion in the urine, it is only possible to make use of the above method when relatively large amounts of phenol (or other substance) are to be metabolized. There is some evidence, especially in the case of synthetic œstrogens (unpublished results), that large overdosing alters the metabolic path, in that unchanged phenol is excreted. Here large overdosing is likely to give a distorted view of the metabolism, even though the estimation method may be made workable by this means. Obviously, information on the metabolic path taken under normal therapeutic dosing is not necessarily obtained by the method.

In the rabbit, according to Bray, Ryman and Thorpe[1], the normal daily excretion of ethereal sulphate in the urine varies from 10 to 38 mgm. If stilbœstrol, for example, were excreted as its monosulphate, this normal sulphate figure would account for a blank stilbœstrol value of 34–130 mgm. daily. In the case of human urine, the daily excretion of ethereal sulphate may vary from 10 to 250 mgm., corresponding to a daily blank value of 34–840 mgm. stilbœstrol. Since the therapeutic dose of this substance varies from a fraction of a milligram to 50 mgm. daily, and as even 50 mgm. would increase the ethereal sulphate figure by only 15 mgm. (30 mgm. if disulphate were excreted), it is obvious that the metabolism of stilbœstrol in the human subject cannot be studied conveniently by ethereal sulphate determinations.

The same considerations apply to the use of glucuronic acid determinations for following glucuronide formation in metabolism experiments in the human subject.

In order to carry out the experiments on synthetic œstrogen metabolism in therapeutic doses in animals and man at present being conducted in this Institute, it has been necessary to devise chemical separation methods checked by bioassay[2,3,4]. This, too, has disadvantages, yet they are considered less than those outlined above.

Although it has not yet been possible to isolate either the œstrogen glucuronide or the sulphate ester from the urine of patients treated with stilbœstrol or hexœstrol, on account of the small dosages used, yet indirect evidence points to a monoglucuronide excretion of as much as 50 per cent administered œstrogen and a sulphate ester excretion up to 6 per cent. In most cases less than 1·0 per cent œstrogen was excreted in the free form. It was formerly thought that large proportions of synthetic œstrogens administered to man were degraded to completely inactive products.

Full details will be published elsewhere.

A New Blood-Pressure Principle of the Anterior Lobe of the Pituitary

Hitherto only the posterior lobe of the pituitary was known to contain a blood-pressure principle generally called vasopressin. Its role in the circulation system is not defined, and it is not held to be of great importance. As for the anterior lobe of the pituitary, no blood-pressure factor has been found, although some clinical evidence has pointed to its existence; for example, diseases of pituitary origin like acromegaly, Simmonds disease, Cushing syndrome, and Fröhlich disease are very regularly accompanied by blood-pressure anomalies. Moreover, it has been demonstrated that hypophysectomy in animals leads to low blood pressure. However, as some hormones of the adrenals, such as the adrenalin and the desoxycorticosterone group, have effects on blood pressure, and adrenalectomy is known to be followed by a much lower degree of blood pressure than hypophysectomy, attention has been directed hitherto to the hormones of the adrenals. Another reason for neglecting the pituitary in this respect arose out of the problem connected with the Cushing syndrome, which was increasingly regarded as being related to the adrenals rather than the pituitary.

Clinical observations, the details of which will be given elsewhere, have convinced us that the anterior pituitary lobe must contain a blood-pressure factor which has its share in the regulation of blood pressure not only in pathological but also in physiological circumstances. After extensive experimental work we succeeded in extracting from ox pituitaries a principle which was able to raise to normal levels the blood pressure in rats rendered artificially hypotensial by adrenalectomy. We employed the non-bloody method of Byron and Wilson, which allows

TABLE 1

	Blood pressure before operation	Blood pressure after operation
Rat 1	135 mm. Hg	85 mm. Hg
Rat 2	130 „ „	80 „ „
Rat 3	140 „ „	95 „ „
Rat 4	135 „ „	90 „ „

repeated measurements with the same animal, thus making possible comparable pressure readings on consecutive days. In addition, this method permitted us to determine the duration of the pressure effect and to learn whether, after its disappearance, it can again be reproduced by repeated injections. As an example, we submit some short-term observations made with four adrenalectomized rats, while a fuller account with larger numbers in a modified arrangement will be given in another paper.

Table 1 shows the average blood pressure of each rat taken before and after adrenalectomy and determined by at least five measurements. The injections begin on the second day after adrenalectomy and are continued once a day as long as the rat survives. Considering the fact that the rats cannot be given life-prolonging extracts like adrenal hormones, in order to exclude any mistake with respect to the substance tested, and furthermore taking into account the weakening effect of prolonged narcosis, indispensable in this pressure method, the survival period is only six to eight days. The effect of the injections is observed one to two hours after each injection. The next day the rat is left without an injection and its blood pressure is determined. On the following day another injection is given and its effect observed, and so on until the death of the animal. As may be seen from Table 2, the full pressure effect does not last twenty-four hours, but the blood pressure does not revert to the original low level before treatment. That there is a cumulative effect can be seen from a comparison of the figures in the interval between two injections.

A more detailed paper will give evidence that the remaining mother substance, from which the blood-pressure principle was obtained by dialysis through a 'Cellophane' membrane, did not show any pressure properties. Its passage through colloidal filters indicates a small molecular size of this principle. Its chemical nature has not yet been ascertained, but it seems to belong to the amino-acid group. It could be separated from other pituitary hormones by fractionated dialysis preceded by an acid hydrolysis of ox pituitary (lobe anterior). The concentration used was 1 gm. of fresh gland material, corresponding to 1 c.c. of the final extract.

The effect of this hypophyseal factor is quite different from that of vasopressin and adrenalin. Contrary to these, it does not have an immediate effect but within one or two hours later, and above all it is of lasting and cumulative character. It has more resemblance to the pressure effect of the desoxycorticosterone group, but it differs from the latter in its stronger and more distinct action Preceding the experiments with adrenalectomized rats, we tested this principle with the object o differentiating it from gonadotropin and adrenocorticotropin. Contrary to adrenocorticotropin, i had no stimulating effect on the adrenal cortex and no adrenal enlargement could be recorded b the usual methods.

TABLE 2. BLOOD-PRESSURES (MM. MERCURY)

	First injection		Second injection		Third injection		Fourth injection
	After 2 hr.	After 24 hr.	After 1 hr.	After 24 hr.	After 1 hr.	After 24 hr.	After 2 hr.
Rat 1	125	90	125	110	125	110	125
Rat 2	115	100	125	105	120	120	dead
Rat 3	130	110	140	115	140	dead	
Rat 4	130	110	140	115	140	dead	

From our observations, we arrived at the following conclusions :

(1) The anterior lobe of the pituitary contains blood-pressure principle.

(2) It seems probable that this principle is th cause of blood-pressure anomalies met in certai diseases of the anterior pituitary lobe.

(3) There are indications that this factor has it share in the normal control of blood pressure ; thi would mean that the regulation of blood pressure i partly hormonal.

These investigations were carried out in th laboratories of the Teva Chemical Works, Jerusalem

Influence of Hypophyseal Hormone and o Nervous Impulses on the Colour-dress o Hermaphrodite Teleostean Fish

INJECTION of extracts of the posterior pituitar gland evokes the brilliant colours of the 'nuptia dress' in *Phoxinus lævis*[1] and some marine teleosteans The active principle, intermedin, is produced in th intermediate lobe of the hypophysis[1] and its secretio is probably controlled by a hypothalamic centre In *Phoxinus lævis*, localized destruction of particula regions of the spinal cord delays or inhibits th reaction. From this, some authors[2,4] have conclude that the hormone affects the chromatophores not onl peripherally but also via the central nervous system Others think it more probable that the result c this operation came about through oxygen-want, an that the lipophores of a fish's skin, unlike the melanc phores, are without innervation[5].

The following experiments, carried out on a Adriatic perch, *Serranus scriba*, show the particula sensitivity of the lipophores to intermedin and t nervous impulses. The experiments, save for on series, were performed outside the spawning seasor The fish were kept under approximately equal cor ditions of lighting, oxygenation and temperature The active substances, with one exception, wer dissolved in 0·10 ml. of physiological saline c Ringer's solution and injected subcutaneously i the dorsal region. Specimens injected with saline c Ringer's solution were used as controls.

In *Serranus scriba*, unlike *Phoxinus lævis*, exhibitio of the 'nuptial dress' is not confined to a particula season : many individuals wear the characteristi coloration outside the spawning season. When suc a fish was caught, the 'nuptial dress' often disappeared reappearing later in the aquarium. This phenomeno is not caused by oxygen-want ; for the bright colour frequently disappeared temporarily when the fis were chased about in the oxygenated water, bu persisted after pithing, or after paralysis of th respiratory centre by 0·40 mgm. of atropine sulphate

The effect of excitation appeared more or less immediately and, therefore, is probably a result of direct nervous stimulation. It is questionable whether, in addition, secretion of endogenous adrenalin takes place during excitation. The effect could be reproduced by adrenalin hydrochloride or by 0·05–0·50 mgm. of acetylcholine chloride, which is known to stimulate the adrenal medulla[6]. But the adrenalin was effective only in doses of 0·10 mgm. or more and the individual responses to acetylcholine varied in intensity. 0·20–0·60 mgm. of the sympathomimetic tyramine also caused fading of the 'nuptial dress'; the effect appeared 15–45 minutes after injection, the fish remaining pale for about two hours.

We found, like Fleischmann and Kann, that posterior pituitary extracts evoked the 'nuptial dress' within 10–20 minutes after injection. Doses of 0·50–1·00 I.U. of a whole extract, 0·05–0·10 I.U. of a fraction with predominantly pressor-activity, or 2·00 I.U. of a predominantly oxytocic fraction were effective. The figures show that, on fractionation, the intermedin mainly passes into the pressor-fraction.

In *Serranus scriba* the hormone acts on the lipophores peripherally[2]. Nevertheless, removal of the brain orally from the optic lobes, which affected respiration for a few minutes only, inhibited the response of the erythrophores while that of the xanthophores was somewhat enhanced. This result suggests that the chromatophore response to the action of the hormone may be influenced by the central nervous system. Atropine sulphate, though paralysing the respiratory centre, did not reduce the hormonal effect; the latter seemed actually to be increased in some specimens. Hypophyseal extracts and tyramine inhibited one another in their actions on the colour-dress.

In *Serranus scriba*, pressure on the roof of the pharynx produces no colour-change[2], while in *Phoxinus* this manipulation produces the 'nuptial dress' by release of intermedin[5]. We repeated this experiment on *Serranus scriba* during the spawning season and at various other times of the year, with the same constantly negative result. Furthermore, we injected individuals which were not in 'nuptial dress' with a suspension of *Serranus*-pituitaries in Ringer's solution. These injections produced no colour-change, whether the donors were in 'nuptial dress' or not. It follows from this that the hypophysis of *Serranus scriba*, of which the lipophores are so sensitive to intermedin, does not produce this hormone. Moreover, injection of 0·50 ml. of pregnant urine on two consecutive days, representing a total dose of about 15 M.U. of chorionic gonadotrophin, did not influence the coloration. This result agrees with that obtained by Fleischmann and Kann, who found that gonadal hormones produce no colour-change in *Serranus scriba* although they do so in the bitterling. These peculiarities become comprehensible when one recalls that this fish, unlike the minnow and the bitterling, is hermaphrodite. Its 'nuptial dress', therefore, represents no sex function, and consequently is not caused, under physiological conditions, by a sex gland. In this connexion, it may be of interest that in *Serranus cabrilla*, a closely related perch, the 'nuptial dress' is much less conspicuous than in *S. scriba* and cannot be produced by intermedin.

This letter is an account of work carried out in the Oceanographic Institute, Split, in 1938–39, its earlier publication having been prevented by the War. One of us (O. P.) gratefully acknowledges the hospitality shown him by the members of the Institute.

Phylogenesis of the Perivascular Spaces of the Brain

According to recent investigations by Van Rijssel[1] on a species of carp (*Carassius Gibelio*), the perivascular spaces penetrate throughout the brain. Cerebrospinal fluid circulates in the spaces, and thus the external and internal liquors mix. This circulation goes in the same direction as the blood circulation and is created by the pulse wave.

In my experiments, I injected a 1 per cent trypan blue solution into the cranial cavity and the ventricles of different vertebrates. In fish (*Leuciscus rutilus*, *Abramis brama*, *Aspius rapax*, *Perca fluviatilis*) I found, in conformance with Van Rijssel's observations[1], that the channels surrounding the blood vessels penetrate throughout the whole of the brain substance and bring about a connexion between the surface and the ventricles of the brain. This channel system is best defined in the pallium, which is densely interwoven with a network of perpendicular blood vessels. I made similar observations in amphibians (*Rana esculenta*, *Rana ridibunda*).

Among the reptiles, I investigated the brains of lizards (*Lacerta viridis*). Their hemispheres are more strongly developed, and the perivascular channel system penetrating the brain is very marked (Fig. 1). The liquor externus appearing in Teleostii is represented in reptiles by a continuous layer of fluid around the brain, increasing the significance of the perivascular spaces. The arteries enter from the surface of the brain or from the inter-hemispherical fissure and penetrate the substance of the brain perpendicularly.

They turn again at right angles on reaching the ventricle, and in the subependymal layer they continue

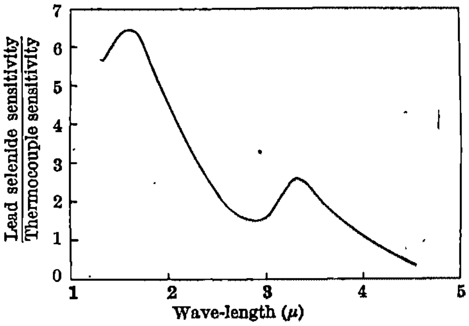
Lead Selenide Cells for Infra-Red Spectroscopy

THE advantages of lead sulphide cells[1] as detectors in infra-red spectrometers have already been described[2] for the region between 1 and 3 μ. Although it appears that the useful range of these cells may be extended slightly by working at liquid air and liquid hydrogen temperatures[3], it seemed to us more profitable to explore further the possibilities of lead selenide cells as a means of extending the range of photoconductive methods in the infra-red. Reports of war-time work in Germany indicated that lead selenide had a peak sensitivity near 3·4 μ as compared with the lead sulphide peak near 2·6 μ; but no figures have been available on the actual performance of these German cells, relative to some standard such as a good vacuum thermocouple. The fact that lead selenide cells never got beyond the laboratory stage in Germany would seem to indicate that progress there had not reached the stage where the lead selenide cell was superior to the thermocouple or bolometer.

We have recently made lead selenide cells by the method outlined by Simpson[4] which are superior to a Hilger–Schwarz thermocouple, at least as far as 4 μ, and have a time of response which is well below 50×10^{-6} sec. These have been tested in a prism spectrometer (lithium fluoride prism) of high resolving power against a first-rate Hilger–Schwarz vacuum thermocouple as standard. By comparing the slit widths necessary to give the same signal/noise ratio when the thermocouple has a 'Pyrex' window in front, of comparable thickness to the base of the lead selenide cell, we obtained the sensitivity curve shown in the graph. It will be observed that the lead selenide cell has two maxima of sensitivity, one near 1·6 μ and the other near 3·3 μ, the former being considerably the higher of the two. The factors controlling the relative heights of these two maxima have not yet been elucidated.



Although the lead selenide cells so far made are inferior in performance to lead sulphide cells (comparing absolute sensitivities at their respective maxima) we have no reason to believe that the optimum method of preparation and usage has yet been achieved. These preliminary results are, however, most encouraging, and even if no further improvement is obtained the present lead selenide cells are an important advance on the lead sulphide cell. The extension of the usable range from 3 μ to 4 μ means that virtually all absorption bands due to the stretching vibrations of hydrogen atoms can be examined with a much higher resolving power and at much greater speed than was previously possible. The 'Pyrex' envelope now used is admittedly a drawback in that its absorption limits the effective range to 3·4 μ, but we have found that a quartz envelope gives an improvement, and it is hoped that a suitable window can be arranged for the base of the envelope to enable the full range to be exploited.

We are indebted to the Admiralty and to the Telecommunications Research Establishment at Malvern for the loan of equipment used in making and testing these cells.

Interaction Terms in Molecular Vibrations

WE have recently been investigating the magnitudes and signs of the interaction terms in the potential functions of triatomic molecules *XYZ*. These arise from interactions between two bond-lengths (*XY* and *YZ*), or between one bond-length and the angle *XYZ*. In our study of these terms we have distinguished three distinct effects: (1) resonance effects; (2) interaction between non-bonded atoms (here *X* and *Z*); (3) changes of hybridization at the central atom (here *Y*). A proper understanding of all three of these is necessary before even the signs of the interaction terms can be adequately explained.

An example of each of these three effects may be given.

(1) The resonance effect is shown in the linear molecule N—N—O, where the chief resonating structures are I and II,

$$\overset{-}{N}=\overset{+}{N}=O \qquad N\equiv\overset{+}{N}-\overset{-}{O}$$

(I) (II)

and the wave function is

$$\psi = \psi_I + \lambda\psi_{II}.$$

If, now, the N—O bond-length is increased (by Δr_1), ψ_{II} is favoured energetically, so that λ is increased and the structure II acquires greater importance. This means, as has been mentioned elsewhere[1], a shortening of the N—N bond (by Δr_2) and consequently a positive f_{12} in the potential energy expression for linear vibrations:

$$2V = f_1 \overline{\Delta r_1}^2 + f_2 \overline{\Delta r_2}^2 + 2 f_{12}\, \Delta r_1\, \Delta r_2.$$

This sign for f_{12} agrees with the vibration spectrum[1].

(2) The interaction between non-bonded atoms is shown in the linear molecule H—C≡N. Here the dipole moment for both bonds is directed in the same way (+→), so that H is positively charged and N is negatively charged. There is, therefore, a strong attraction between them. It can be shown that this leads to a negative value of f_{12}, in agreement with experiment[2].

(3) The changes in hybridization at the central atom are illustrated by the water-molecule H—O—H.

In the equilibrium configuration the HOH angle is about 104° 31′, and there is very little *s*, and almost all *p*, in the hybridized oxygen orbital from which the O—H bond is formed. But if the angle is increased, it can be shown[3] that the amount of *s* increases and consequently the new equilibrium bond-length decreases. This implies that in the potential energy formula,

$$2V = f_1\,[\overline{\Delta r}_1{}^2 + \overline{\Delta r}_2{}^2] + 2f_{12}\,\Delta r_1\,\Delta r_2 + r_1 r_2 f_\theta\,\overline{\Delta\theta}^2 + 2r_1 g_c\,(\Delta r_1 + \Delta r_2)\,\Delta\theta,$$

the bond-angle interaction constant g_c has a positive value. This again is in agreement with observation[4].

It is worth while noticing furthermore that we have been able to show that the contributions to the interaction constants f_{12} and g_c that arise from the force between the two non-bonded atoms have the same sign, though this sign is negative when the force is attractive and positive when it is repulsive.

In general, two or more of the effects (1)–(3) above will act at the same time. But it is often possible to predict the sign and approximate magnitude of the interaction constants: and if these constants have been determined experimentally, we are able to interpret them in terms of more fundamental notions, namely, the description of electron behaviour by means of (1)–(3).

A full account of this work will be published later.

Nuclear Forces and the Magnetic Moment of the Deuteron

RECENTLY[1] the magnetic moments of the proton, neutron and deuteron have been measured with great precision. It is found that the moment of the deuteron differs from the algebraical sum of the moments of the proton and neutron by an amount much greater than the experimental error. The discovery of the electric quadrupole moment of the deuteron[2] in 1939 already indicated that the ground-state of the deuteron is not of pure ^3S character but contains an admixture of ^3D. The observed magnetic moment can be explained if the percentage admixture is 4 per cent. If it can be assumed that relativistic effects are unimportant[3], use may be made of this accurate figure to obtain further information about the neutron-proton interaction. Following the method of Rarita and Schwinger[4] we have taken this to be of the form

$$V(r, \sigma_1, \sigma_2) = -\{(1 - \tfrac{1}{2}g) + \tfrac{1}{2}g\vec{\sigma}_1.\vec{\sigma}_2 + \gamma S\}Cf(r/a),$$

where

$$S = \frac{3\vec{\sigma}_1 . \vec{r}\,\vec{\sigma}_2 . \vec{r}}{r^2} - \vec{\sigma}_1 . \vec{\sigma}_2,$$

$\vec{\sigma}_1$, $\vec{\sigma}_2$ being the spin vectors of the respective nucleons and r their relative co-ordinate. This interaction involves four constants, g, γ, the range a and the strength C of the radial function $f(r/a)$. For a given function, f, the constants may be fixed completely from the collision cross-section of thermal neutrons with protons, the binding energy and quadrupole moment of the deuteron, and the new precise values of the magnetic moments.

Column (*a*) in the accompanying table gives the range derived in this way for four forms of the function $f(r/a)$—the spherical well $f(r/a) = 1$, $r < a$; $= 0$, $r > a$, the Gaussian potential $\exp(-r^2/a^2)$; the Yukawa potential $\{\exp(-r/a)\}(a/r)$; and the exponential potential $-\exp(-2r/a)$. The value for the spherical well case has already been obtained by Rarita and Schwinger[4]. The inclusion of an exchange operator in the function has no influence on these results.

Independent evidence concerning the range may be obtained by choosing a different quantity in place of the magnetic moment to complete the determination of the four constants. The first of these, which gives the ranges in column (*b*) of the table, is the cross-section for elastic collisions of 1–6 MeV. neutrons with protons[5]. In this case the presence or otherwise of an exchange operator does modify the results. The ranges we have given have been obtained with such an operator included. They would otherwise be smaller.

Assumed force law	(*a*) From magnetic moments	Derived range in 10^{-13} cm. (*b*) From scattering of 1–6 MeV. neutrons by protons	(*c*) From proton-proton scattering	(*d*) From triton binding energy
Spherical well	2·8	2·45±0·1	2·8	
Gaussian	1·9±0·15	—	1·94	2·22[7]
Yukawa	1·4±0·05	1·8 ±0·05	$1{\cdot}18_5$	$1{\cdot}83_5$[7]
Exponential	1·6±0·05	1·75±0·05	1·73	1·73[8]

In column (*a*) the errors assigned allow for inaccuracy in extrapolation of calculated results; in column (*b*) for experimental error.

If it is assumed that the force between two nucleons is the same whether they are like or unlike, the anomalous scattering of protons by protons or the binding energy of the triton may also be used to provide the fourth relation necessary to fix the range. The ranges obtained from proton-proton scattering by Hoisington, Share and Breit[6] are given in column (*c*) of the table, and those from the triton binding energy in column (*d*). In neither of these cases does the result depend on the presence or otherwise of an exchange operator, but the binding energy calculations have assumed the forces to be central[9] and of exclusively two-body character. (The binding energy of He[4] seems to be slightly too large when calculated with the assumed ranges of column (*d*) (see refs. 8 and 9). This may indicate the presence of repulsive many-body forces.)

It will be seen that, while the results of the different methods are reasonably consistent for three of the radial forms assumed, the Yukawa potential appears quite unsatisfactory in this respect.

A detailed account of this work, including a discussion of the photo-disintegration of the deuteron and the angular distribution of protons projected by neutrons in the range 2–20 MeV., will be submitted shortly for publication in the *Proceedings of the Royal Society*.

Crystal Structures of Zinc and Magnesium Benzene Sulphonates

A RECENT note by A. Hargreaves[1], of the Physics Department, College of Technology, Manchester, summarized the information obtained from a projection, along the b-axis, of the electron density in the unit cell of zinc p-toluenesulphonate. An investigation of the structures of the closely related zinc and magnesium benzene sulphonates, begun by one of us (A. D. I. N.) at Manchester at the suggestion of Dr. Hargreaves and with his assistance, has now been completed in this Laboratory. The positions of all the atoms in the unit cells have been determined by Fourier syntheses of projections of the electron density along the b- and c-axes. The crystals used in this analysis were twinned across the face (100), with the consequence that reflexions (h00) of the twin components overlapped completely, (h05) reflexions were superposed, and there was partial overlap of reflexions (h04) and (h06). Some reduction in the accuracy of the b-axis projection results from the necessity for applying a correction to the observed intensities of these overlapping reflexions.

As was expected, the structures of the benzene sulphonates prove to be essentially similar to that suggested for zinc p-toluenesulphonate by Hargreaves from his partial determination of the structure by means of the single projection along the b-axis. The metal atoms are surrounded by regular octahedra of water molecules, and the metal-to-water distances are in accordance with accepted values of the atomic radii. The benzene ring is plane and the average distance between the carbon atoms is 1·40 A. The sulphur–oxygen bond distance in the sulphonate group is 1·41 A., and the sulphur atom is linked to the benzene ring by a bond of length 1·89 A. in the magnesium compound and 1·81 A. in the zinc compound, the difference probably representing experimental error. The distribution of bonds about the sulphur atom appears to be regular tetrahedral, the bond angles in both compounds being approximately 109°.

The analysis, and details of the structure, will be published elsewhere.

A Rapid Method of Analysis for Certain Surface-Active Agents

THE fact that certain cationic surface-active agents, such as cetyl pyridinium bromide, form stoichiometric salts with anionic surface-active agents such as the alkyl sulphates, alkyl sulphonates and alkyl aryl sulphonates, has been used as the basis of two titrimetric methods of analysis of the latter materials. That of Hartley and Runnicles[1] uses bromphenol blue as an indicator to detect when excess cation-active material has been added, while that of Preston[2] uses a remarkable surface tension change to mark the end-point. Unfortunately, neither method of determining the equivalence point is completely satisfactory. In the first case the colour change is not sharp, and in the second the point at which the surface tension change occurs is affected by the presence of inorganic salts.

In this laboratory we have developed a new method of end-point detection which gives accurate and reproducible results even in the hands of relatively unskilled personnel and under a wide variety of conditions, and does not suffer from the above defects. The method is based on observations by Jones[3]. He showed that whereas the chloride of the basic dyestuff methylene blue is insoluble in chloroform, the alkyl sulphate and related salts are freely soluble and may be extracted quantitatively from aqueous solution by chloroform provided that the chain-length of the organic portion is sufficiently large. (This fact was made the basis of a colorimetric estimation.) However, the extraction is almost completely inhibited if the aqueous phase contains a quantity of cation-active agent more than equivalent to the anionic material present. This is because the colourless cetyl pyridinium alkyl sulphate is more soluble in chloroform and is extracted in preference to the methylene blue salt. The blue colour therefore remains in the upper aqueous layer.

In the new titrimetric method, 10 ml. of an alkyl sulphate or other similar surface-active agent (approximately 0·004 M) is pipetted into a 250-ml. stoppered reagent bottle. 25 ml. of aqueous indicator solution containing 0·003 per cent methylene blue (B.P.), 1·2 per cent sulphuric acid and 5 per cent sodium sulphate are added, followed by 15 ml. chloroform. A solution of cetyl pyridinium bromide (approximately 0·004 M) is then added from a burette. After each small addition of the latter the mixture is shaken. At first the blue colour concentrates in the chloroform layer, but as the titration proceeds there is a slow transfer of colour to the water layer. Later the rate of transfer increases, and eventually the colour of the two layers is visually the same. This is found to be the equivalence point. On further addition the chloroform layer lightens in shade, and becomes colourless.

The fact that the point at which the two layers have the same colour is the equivalence point has been exhaustively confirmed by titrating solutions of some pure sodium alkyl sulphates and many other similar substances of known purity with a cetyl pyridinium bromide solution, the strength of which had been determined by precipitation of its dichromate salt with excess potassium dichromate[4].

The end-point is surprisingly sharp and can be reproduced to 0·1 ml. after a little practice. It is not affected by the presence of excess inorganic salt, acids, moderate quantities of organic solvents, commonly occurring temperature variations, or reasonable departures from the experimental conditions described above.

Substances with chain-lengths greater than C_8 can be determined accurately, but the longer the chain-length the sharper the end-point. Oil-soluble surface-active substances of very long chain-length insoluble in water can be determined by making up the standard solution in chloroform and proceeding as before, except, of course, that the volume of chloroform solution added is measured accurately. Fatty acid soaps and substances having more than one ionizable group cannot be estimated by the method, but their presence does not interfere with its operation with materials to which the method otherwise applies.

A full account of this work will appear shortly elsewhere[5].

I wish to thank the "Shell" Refining and Marketing Co., Ltd., for permission to publish this work, and Messrs. P. J. Garner and S. L. Levy for helpful advice and suggestions.

Reaction of Nitrous Acid with Chlorophyll

Nitrous acid has been found to react readily with chlorophyll, giving four highly coloured crystalline compounds. The reaction was carried out as follows: 10 gm. of chlorophyll (commercial powder) was dissolved in 300 ml. of chloroform and 200 ml. of 3 per cent hydrochloric acid added; 12 gm. of sodium nitrite in 50 ml. of water was then added, with vigorous shaking, over a period of half a minute. The chloroform layer, which underwent a striking colour change from green to dark red, was separated immediately and washed with water. Evaporation of the solvent left a crystalline mass (10 gm.) from which the compounds *A*, *B*, *C* and *D* were obtained

Separation of the Products. *A* and *D* were adsorbed on activated alumina from a chloroform solution of the reaction products. On development with chloroform, *A* formed a red band of its aluminium salt and *D* a yellow band. These bands were separated and the organic constituents obtained from them by boiling with dilute aqueous sodium carbonate, filtering and acidifying the filtrates. *B* and *C* were not adsorbed and were separated by means of boiling 50 per cent alcohol, in which *B* only was soluble. 10 gm. of chlorophyll gave: 1–1·5 gm. of *A*; 3–5 gm. of *B*; 1·5–2 gm. of *C*; and 0·03 gm. of *D*.

Purification. *A* was purified by recrystallization from chloroform – absolute alcohol. *B* was either (i) dissolved in boiling *N*/5 caustic soda and reprecipitated with dilute hydrochloric acid, or preferably (ii) sublimed at 100° C. (20–30 mm. pressure). *C* was crystallized from glacial acetic acid, and then further purified by crystallization from chloroform – absolute alcohol. *D* has not yet been obtained in pure form.

Properties of the Reaction Products. The physical and chemical properties of the substances and the formulæ assigned to them are listed in the table.

Property	*A*	*B*	*C*	*D*
Colour	Indian-red in reflected light, pale yellow-green in transmitted light	Crimson	Indigo	Amber
Crystalline form	Prisms	Needles	Needles	Plates
Odour	Odourless	Smell like *o*-nitrophenol	Odourless	Smell like *o*-nitrophenol
Volatility	Non-volatile	Sublimes and steam-distils	Non-volatile	—
Melting point (corrected	151–153° C.	103·5–105° C.	219–222° C.	(18–28° C.)
Solubility in ordinary organic solvents	Soluble	Soluble	Soluble	Soluble
Solubility in water	Insoluble	Insoluble	Insoluble	Insoluble
Solubility in alkalis	Soluble	Soluble	Insoluble	Soluble
Solubility in 50 per cent ethanol	Soluble	Soluble hot	Insoluble	Insoluble
Tautomerism	Acid-alkali forms	Acid-alkali forms	No tautomerism observed	—
Salt formation	Potassium salt, no sodium salt, no platinichloride	No salts	No salts	—
Reaction with acetic anhydride	Mono-acetyl derivative, orange prisms, m.p. 113·5–115° C.	Mono-acetyl derivative, deep orange prisms, m.p. 76–79° C. DD	No acetyl derivative	—
Formula assigned	$C_{14}H_{13}N_3O_3$	$C_{14}H_{16}N_2O$	$C_{13}H_{10}NO$ or $C_{12}H_{11}NO$ (empirical formula)	—

The compounds *A*, *B* and *C* appear to be tetra-substituted pyrrole derivatives. Further work on the structure of the compounds will be undertaken.

This investigation originated from previous work in South Africa on *Tribulus* poisoning ('geeldikkop') in sheep, associated with symptoms of jaundice and photosensitization. Full details will be published in the *Onderstepoort Journal of Veterinary Science and Animal Industry*.

Occurrence of Microflora in the Salt Pseudomorph Beds, Salt Range, Punjab

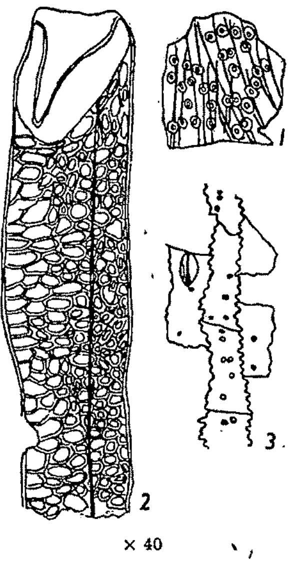
The age of the Punjab Saline Series is still a vexed problem in Indian geology. Gee[1,2,3,4] and Fox[5], to whom we are indebted for much of our geological knowledge of this area, have assigned a 'Cambrian' or 'pre-Cambrian' age to this series. Sahni[6,7,8] and Sahni and Trivedi[10,11], on the other hand, from the evidence of such microfossils, for example, woods of conifers, cuticles of grasses, angiospermous wood elements, etc., and their repeated occurrence at widely different localities, are against a 'Cambrian' or 'pre-Cambrian' age. Two lively symposia were held in December 1944 and 1945 at Poona and at Udaipur, respectively, and a vast literature has accumulated on the subject[8,9,12].

In view of the great scientific importance of the problem a field-party of geologists visited critical sections in the Salt Range in 1944 and re-examined the field evidence in the light of the microfossil data. Their unanimous verdict is that an Eocene or later age for the Saline Series, as suggested by Sahni and others, is irreconcilable with the field evidence, although they were unable to offer any explanation on the occurrence of minute plant fragments of 'post-Cambrian' age in the dolomites and oil shales[13].

We are carrying out investigations on the Salt Range microfossils and have already examined several rocks from the Saline Series of the Dandot overfold, Makrach, Khewra and various other localities. Following the maceration technique, the microfossils recovered from these include: (1) scalariform tracheid of a certain pteridophyte, (2) bordered pitted tracheid of conifer, (3) vessels of angiosperms, (4) libriform fibres of higher dicotyledons, and (5) cuticles. Thus our findings are not all new in relation to the discoveries of Sahni, and far from contradicting him, they firmly support his views regarding the occurrence of such plant-remains in the Saline Series.

But the chief interest in our work lies in the occurrence of a few microfossils in the Salt Pseudomorph Beds, which were so long regarded as unfossiliferous. The argillaceous, fine-textured sandstones and sandy dolomite analysed from this series came from Chittidil, and the microfossils recovered are again mainly those which suggest a Tertiary age. The microfossils recovered from these Salt Pseudomorph strata include wood elements of conifers and angiosperms, cuticles, spores, etc. The following is a provisional list.

(*a*) *Wood elements* (seven types). Tracheids uniseriate to biseriate with bordered pits (coniferous), and scalariform thickening with rays (pteridophytic); angiosperm vessels with alternate pitting, overlaid internally by tertiary thickenings (dicotyledonous) (Fig. 1) or crowded and thus becoming angular due to lateral contact (Fig. 2); wood parenchyma with simple pitting and of isodiametric dimension (coniferous) or of longitudinal cells grouped in series.



× 40

(*b*) *Cuticle* (one type). With sinuous wall and pitted cells and a single stoma, probably of grass (Fig. 3).

(*c*) *Spores* (six types). Two-winged spores with variable bodies and wings (two types), and pollen grains with (1) prominent exine, (2) germ pores, (3) two-ribbed elliptic body, and (4) in tetrad.

Further investigation is in progress, and a detailed note on the subject will be published later.

Our thanks are due to Dr. E. R. Gee, of the Geological Survey of Pakistan, who was kind enough to send us 'Salt Range' rocks from his personal collections for analysis.

Number of Self-Sterility Alleles

In a note in *Nature* of September 6 [1], A. J. Bateman gives an interesting estimate of the number of *S*-alleles in a freely interbreeding population of self-incompatible plants, using the data of the late R. D. Williams[2]. In one sample of 25* plants, 36 alleles had occurred once only and 7 twice, while in a sample of 22 from a second variety, 38 had occurred once and 3 twice.

If a is the frequency of occurrence of any allele in a sample of N plants, we have for the two varieties

	$S\{a(a-1)\}$	$N(N-1)$
First variety	14	600
Second variety	6	462
Together	20	1062

Bateman, rightly in my opinion, calculates the ratio of the two columns, and finds in four times this ratio, or $n = 212{\cdot}4$, a reasonable estimate for the total number of alleles in each variety, when the evidence of the two samples is pooled, and if all alleles have the same frequency. The estimate by maximum likelihood is 197.

He adds, however, a 5 per cent upper fiducial limit of 442 alleles, expressing the opinion that the error in the calculation due to the variance in the frequencies of the different alleles is unlikely to be large compared with the sampling errors. I do not think, on these data, that such an upper limit can be given, although the lower limit is not open to this objection.

To take a simple model, if the frequencies of the different alleles were in geometric progression, with common ratio r, the expected value of $1/n$, as calculated above, would be

$$\frac{(1 - r^2)(1 + 2r^2)}{2(1 + r^2)(1 + r + r^2)},$$

even if the number of alleles were infinite. This gives an estimate for r between 0·990 and 0·991, so that the observed repetitions could be fully accounted for, even if the number of alleles were infinite (as in a finite population it cannot indeed be), provided the commonest alleles approach about 1 per cent in gene frequency.

Sclerotinia Porri on *Allium* spp. in England

WHILE working at Cambridge, Mrs. R. H. Richens found that plants of crow garlic, *Allium vineale*, examined in June and July, were often attacked by a species of *Botrytis*. Cultures of this fungus, made on Dox's agar in July 1946, have produced both *Botrytis* conidiophores and apothecia.

The conidiophores were short and the conidia measured 8–17 μ × 6–11 μ, averaging 11·7 μ × 8·6 μ. Mature ascospores were hyaline, markedly elliptical, normally with oil globules at both ends, and measured 11–25 μ × 6–11 μ, the average being 17·0 μ × 7·8 μ. The apothecia were large, up to more than 30 mm. in height and 12 mm. in disk diameter, and characterized by a dense mat of fine hairs over the lower portions of the stipes. The size of the apothecia varied with that of the sclerotia from which they grew, the largest being produced on large sclerotia, up to 15 mm. in length and 8 mm. in height.

In culture, the fungus produced abundant raised, fluffy, white mycelium. Conidial production was late and sparse, and a few small sclerotia were produced, also after some delay. In addition, many cultures produced one or two large, raised, irregular, 'convoluted' sclerotia. The mycelial felt was more pronounced and conidiophores almost absent in cultures on potato dextrose agar.

Single-ascospore cultures produced conidia, confirming the connexion between the *Botrytis* and the apothecia. Onions (*Allium cepa*) inoculated with the fungus developed a severe neck rot on which mycelial felt and sclerotia were predominant, conidia being few in number or absent. When inoculum which had been subcultured twice and carried in culture for three months was used, neck rot was not produced, indicating that the fungus may lose pathogenicity in culture.

Both the *Botrytis* and the apothecial stages of this fungus agree in their characters with *Sclerotinia Porri*, recorded on leek seed by van Beyma Thoe Kingma[1]. This is thought to be the first record of that species in England and on *Allium vineale*. It is interesting to note, however, that the *Botrytis* stage also agrees with the published data for *Botrytis byssoidea* Walker[2], which was recorded in England by Croxall and Pickford[3]. Walker states that this species loses pathogenicity in culture. It seems possible, therefore, that *Sclerotinia Porri* may be the perfect stage of *Botrytis byssoidea*, but further work will be necessary to determine this.

I am particularly indebted to Dr. W. A. R. Dillon Weston, who supervised this work, for much helpful advice and guidance. My thanks are also due to Dr. and Mrs. R. H. Richens for providing the diseased material, to Dr. A. Smith for suggesting that I should obtain it, to Dr. W. J. Dowson for advice and criticism, and to Prof. Johanna Westerdijk of Baarn for assistance in confirming the identity of the species. I also wish to acknowledge financial assistance from the Agricultural Research Council.

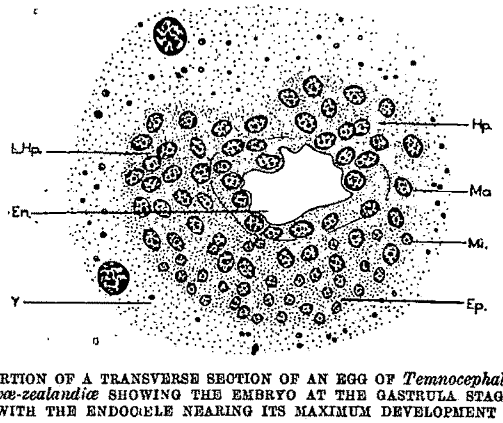
Embryology of *Temnocephala novæ-zealandiæ* Haswell

THE egg of *Temnocephala novæ-zealandiæ* consists of a zygote surrounded by polyhedral-shaped yolk cells. First cleavage results in the formation of a macromere and a micromere. The macromere divides into another macromere and a micromere, and after this three-celled stage each cell divides evenly and repeatedly, producing a large number of macromeres and micromeres. These constitute the blastoderm and are centrally situated in the yolk mass, which now is a syncytium (*Y*). When fully formed, the blastoderm is also syncytial in nature, thus necessitating the description of its component cells as macronuclei (*Ma*) and micronuclei (*Mi*). Two germinal layers are recognized. The macronuclei give rise to the œsophagus, intestine, reproductive organs and excretory apparatus and are regarded as belonging to the hypoblast (*Hp*). The micronuclei give rise to the nervous system, pharynx and body-wall and are regarded as epiblastic (*Ep*).

The gastrula stage is characterized by the formation of an endocœle (*En*). This cavity is presumably homologous with the archenteron, because it is the first cavity formed in the embryo of two germinal layers, it is hypoblastic, it afterwards forms the post-epiblastic portion of the alimentary canal and is persistent throughout the life of the animal.



PORTION OF A TRANSVERSE SECTION OF AN EGG OF *Temnocephala novæ-zealandiæ* SHOWING THE EMBRYO AT THE GASTRULA STAGE WITH THE ENDOCŒLE NEARING ITS MAXIMUM DEVELOPMENT

En, endocœle; *Ep*, epiblast; *Hp*, hypoblast; *L.Hp*, lateral hypoblastic band; *Ma*, macronucleus; *Mi*, micronucleus; *Y*, yolk syncytium

At its maximum development the endocœle extends for one third of the length of the egg, and at this stage organ-rudiments appear. Well-defined regions of hypoblast lie one on either side of the endocœle (*L.Hp*) and one on the ventral side. The epiblast partially segregates into a region anterior to the endocœle, another on its antero-ventral aspect and a third ventral to the ventral hypoblastic band. The three hypoblastic bands extend posteriorly to form the reproductive organs, while anteriorly they develop into excretory system rudiments. The ventral epiblastic band forms the body-wall by the migration of its cells through the yolk to the periphery of the egg. The anterior epiblastic region is the nervous system rudiment and the antero-ventral region is the pharyngeal rudiment.

The endocœle now undergoes marked reduction in size and the pharynx develops a large lumen. These two cavities unite and the endocœle thus becomes the œsophagus. Cells from the wall of the œsophagus proliferate and form an intestinal wall enclosing most of the remaining yolk material. At hatching, all internal organs have developed into a functional state except the reproductive systems.

A fuller account is being published elsewhere.

Coiling of Wool Induced by Certain Reagents

DURING some investigations regarding twist in wool, some observations worth describing were made, though no explanation can be offered.

If a Merino wool fibre 4 in. long is anchored at each end and allowed to lie loosely in a horizontal position in a Petri dish in water, nothing obvious results. If the water is replaced with 1 per cent caustic soda (20° C.) several phenomena may be observed. Thus: (1) within 1 min. the original crimp disappears and the fibre appears 'lank'; (2) it goes into about three coils per inch within 3 min.; (3) it goes into fine turns within 8 min.; (4) it winds up more closely, averaging 15–20 turns per inch by 15 min., after which no further action is observed; (5) the direction of the coil reverses here and there along the length of the fibre.

No similar phenomena were observed in acid solutions.

If, after immersion for 15 min. in 1 per cent sodium hydroxide, the fibre is transferred to water or acid, the coils unwind; they reappear when the fibre is replaced in the sodium hydroxide solution. But if the period of immersion is two hours or more, the coils do not disappear in acid or water.

Human hair, produced in a relatively straight follicle, does not coil in a solution of 1 per cent sodium hydroxide; primary wool fibres, produced in relatively spiral follicles, go into large coils; secondary wool fibres, which come from coiled follicles, go into very close coils. No closer correlation has yet been made on this point. Wools of breeds other than the Merino behave similarly in all these respects but are less predictable as to behaviour.

It was found that under zero tension there was a 2–3 per cent decrease from the original length after immersion for 15 min. in 1 per cent caustic soda. If this were prevented for 24 hours by anchoring the fibre in the caustic soda at its original length, it will not assume fine coils when, afterwards, the ends are moved closer together, but it goes into a few irregular large coils.

Large irregular coils resulted from using the following solutions at 20° C.: 1 or 3 per cent potassium cyanide, 1 per cent sodium thioglycollate, and 0·125 and 0·33 per cent sodium sulphide and 0·88 S.G. ammonium hydroxide. 1 per cent potassium hydroxide gave results similar to 1 per cent sodium hydroxide, but barium hydroxide was not effective in this respect.

Merino wool in 1 per cent sodium sulphide (anhydrous salt) at 20° C. was then studied under similar conditions. In this solution the fibres immediately straighten out and remain straight for 1 min. They assume large coils within 3 min., and are very closely coiled in 6 min. (if transferred to water at this stage these coils disappear but reappear when again immersed in the sulphide solution), and 10 min. after immersion they again straighten. The fibres once more wind up into very fine coils 15 min. after immersion and may then disintegrate. The lengths of six Leicester fibres, which at no stage have been under tension, had increased finally in 1 per cent sodium sulphide between 33 and 56 per cent, averaging 47 per cent.

The action of 1 per cent caustic soda may be due to a high *p*H, and the further reactions of 1 per cent sodium sulphide may be due to subsequent reduction. Treatment of fibres with 1 per cent caustic soda for 15 min., followed by a wash in water which causes them to uncoil, and subsequent immersion in 1 per cent sodium sulphide resulted in the characteristic coiling, straightening and further coiling that has been described for 1 per cent sodium sulphide. Treatment of fibres with 1 per cent sodium sulphide until the *first* coiling has been completed (6 min.), followed by a wash in water and immersion in 1 per cent caustic soda, caused coiling similar to that previously permitted for these fibres in the 1 per cent sodium sulphide, but no subsequent straightening or further coiling as would be the case were sodium sulphide used finally instead of 1 per cent caustic soda. Treatment of fibres for 6 hours with 1 per cent caustic soda did not prevent them when afterwards immersed in 1 per cent sodium sulphide from straightening out and then coiling as described earlier. Such fibres, however, did not disintegrate and would bear weights of 0·1–0·2 gm. without undue stretching. This is in marked contrast to the eventual gelatinous nature of wool immersed in 1 per cent sodium sulphide without previous prolonged treatment with 1 per cent caustic soda. It is evident that the prolonged action of the 1 per cent caustic soda makes the wool resistant to the disintegrating action of 1 per cent sodium sulphide.

Obviously, further fundamental chemical, physical and histological studies must be completed before attempting to explain the phenomena described. The purpose of this note is to direct the attention of other workers to these facts so that they also may investigate what are indeed some very peculiar characteristics of wool.

ANTITUBERCULAR ACTIVITY OF DIPHENYL ETHERS AND RELATED COMPOUNDS

By Dr. VINCENT C. BARRY, L. O'ROURKE

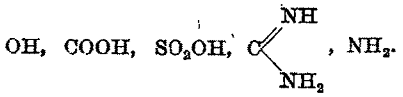
AND

D. TWOMEY

Department of Chemistry, University College, Dublin

IN a previous communication in *Nature*[1], the inhibitory effect of soluble diploicin derivatives on the growth of the tubercle bacillus *in vitro* was described, and it was suggested that simpler diphenyl ether derivatives might also exhibit antitubercular properties. We have now prepared a variety of diphenyl ether derivatives as well as some related compounds in which the oxygen link has been replaced by $-O(CH_2)_n-$, $>CO$, etc. Several of these comparatively simple compounds are much more active than derivatives of diploicin. This activity against Mycobacteria is also shared by diphenylene oxide derivatives.

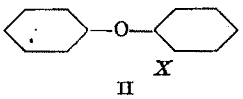
The first group of compounds examined by us were of the type I, where *X* represents a solubilizing group, for example,



$$OH,\ COOH,\ SO_2OH,\ C\begin{matrix}\nearrow NH\\ \searrow NH_2\end{matrix},\ NH_2.$$

All the compounds of this type inhibit the growth of Mycobacteria in nutrient broth; but by far the most active were *p*-hydroxydiphenyl ether and *p*-aminodiphenyl ether (as the hydrochloride) which completely inhibits *Myco. smegmatis* at 1/100,000 and *Myco. tuberculosis* for six weeks at 1/35,000, while the *para* sulphonic or carboxylic acid derivative ($X = -SO_2OH$ or $-COOH$) showed no inhibition at 1/1,000. When the solubilizing group occupies the position *ortho* to the ether link, the activity is much reduced (II): thus 2-amino diphenyl ether (hydrochloride) completely inhibits the tubercle bacillus at 1/10,000.

I



II

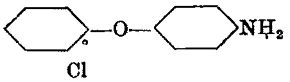
The substitution of two polar groupings in the *para* positions of diphenyl ether leads to molecules with low antitubercular activity.

1/4,000

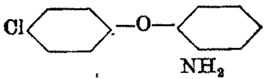
1/6,000

On the other hand, the introduction of a halogen atom into the second benzene nucleus in I or II produces compounds with considerably enhanced activity in I but not in II, as shown.

1/110,000

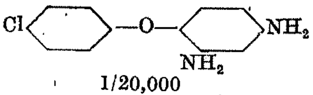


1/150,000

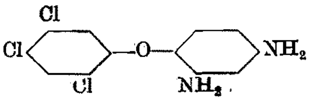


1/15,000

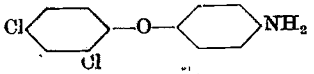
Halogen substitution will not, however, lead to active molecules if two amino-groups are present in one benzene nucleus. Two halogen atoms in the unsubstituted ring of I give a very active compound.



1/20,000

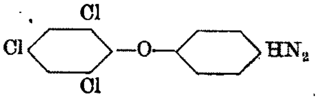


1/25,000

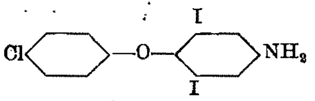


1/600,000

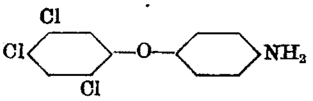
The effect of a further increase in the degree of halogenation on the antitubercular activity of these compounds is, at least at the moment, unpredictable. Thus the substitution of three halogen atoms in one benzene ring or divided between the two rings in I leads to strongly active molecules which may, however, differ considerably in activity.



1/250,000

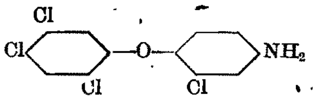


1/225,000



1/1,000,000

Again, a compound with four halogen substituents may show on the whole a comparable activity.



1/1,000,000

While it is not safe at this stage to make any final deductions relating structure and antitubercular activity in these highly halogenated compounds, it is noteworthy that a more symmetrical disposition of halogens may not occur in the molecules possessing greater inhibitory activity.

The enhancement of biological activity consequent on the introduction of halogen atoms is not confined to amino-diphenyl ethers but occurs also with other derivatives.

inactive at 1/1,000

1/75,000

1/100,000

1/300,000

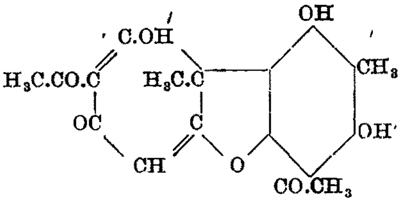
Replacement of the amino- by the amidino-group in I weakens the antibacterial activity. Chlorinated derivatives of amidino-diphenyl ether are at present being examined. These compounds were kindly placed at our disposal by Dr. A. J. Ewins, director of research to May and Baker, Ltd. The effect of substituting other groups in I and II has been examined to a limited extent but will not be dealt with here. Walter has examined[2] a large number of hydroxydiphenyl ethers for antibacterial properties. The test organisms employed in his case were *Staphylococcus aureus* and *Bact. coli*, and none of his compounds contained aromatic amino-groups. In his derivatives, the oxygen link could be replaced by S, Se, NH or CH$_2$ while still retaining the same order of biological activity. We have not yet tested adequately similar modifications of our molecules.

It is of interest that compounds of the type shown in III also display considerable antitubercular activity.

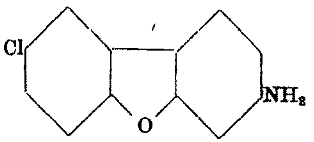
III

The compound derived from phenylethyl alcohol ($n = 2$) has an inhibitory dilution of 1/150,000. This compound is of peculiar interest, as Goris and Sabetay have recently reported[3] the isolation of phenyl ethyl alcohol from tubercle bacilli and have attributed the characteristic odour of the bacilli, at least in part, to the presence of this substance. The effect of introducing halogen atoms into the benzene nuclei in this series has not yet been tested.

Antitubercular activity extends also to simple derivatives of diphenylene oxide (IV). Marshak has recently described[4] the isolation of a yellow crystalline substance from the lichen *Ramalina reticulata*. He has shown that this substance inhibits the growth *in vitro* of *Myco. tuberculosis* and exercises a suppressive effect on tuberculous infection in guinea pigs. While Marshak calls this substance 'Ramalina crystals', the analyses and properties of the substance as given by him correspond closely with what would be expected for *usnic acid*. (These views have been communicated privately to Dr. Marshak, who has confirmed the identity of his material with usnic acid[5].) It has been shown in this laboratory that usnic acid does inhibit strongly the growth of *Myco. tuberculosis in vitro* and that it retains to a considerable extent this activity in the presence of 5 per cent human serum. From the structure shown, which was suggested tentatively by Curd and Robertson[6], it will be seen that usnic acid has the skeleton structure of a diphenylene oxide derivative. This fits in remarkably with our experience of compounds of this type. 2-Amino-diphenylene oxide in the form of its hydrochloride inhibits the growth of the tubercle bacillus at 1/100,000, while its monochlorinated (or brominated) derivative (IV) causes complete inhibition at 1/400,000 and partial inhibition at 1/1,000,000. The position of the halogen atom in IV has been established[7].



Usnic acid
1/500,000



IV
1/400,000

This account gives some idea of the remarkable antitubercular activity exercised *in vitro* by these relatively simple compounds. It will not be possible, however, to draw final conclusions as to the relationship existing, in these related series, between constitution and anti-tubercular activity until a very great number of compounds has been prepared and examined.

This investigation is being conducted under the auspices of the Medical Research Council of Ireland, and the biological tests were carried out by Dr. P. A. McNally, Trinity College, Dublin, to whom grateful acknowledgment is made.

APPLICATION OF FILTER PAPER PARTITION CHROMATOGRAPHY TO RADIOACTIVE TRACER STUDIES

By Dr. R. M. FINK, Dr. C. E. DENT*
AND
K. FINK

Departments of Radiology and Pathology, University of Rochester, Rochester, New York

THE filter paper chromatographic procedure developed by Consden, Gordon and Martin[1] has proved to be very useful in the qualitative and semi-quantitative analysis of amino-acid mixtures, and appears to have possibilities for extension to a variety of other compounds[2,3].

* Rockefeller Fellow on leave of absence from University College Hospital, London.

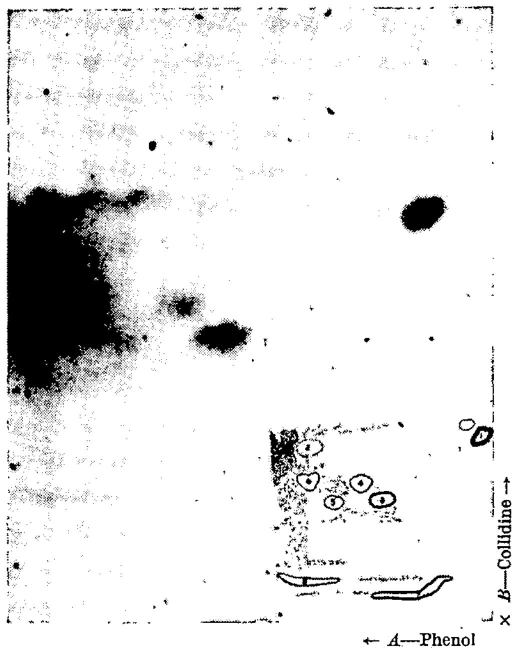

Fig. 1

It was believed that the technique would also be useful if it could be applied to the study of the metabolic fate of compounds labelled with radioactive isotopes. Radio-iodine (I^{131}, half-life 8·0 days) was immediately available and seemed a reasonable choice of isotope for testing the feasibility of using paper chromatography in conjunction with radio-autography, since it gives off a moderately penetrating beta ray (0·6 Mev.), and a reasonably large proportion of the dose can be recovered in the small amount of tissue hydrolysate that has to be used in order to avoid overloading a paper chromatogram. A preliminary test in which carrier-free radio-iodide alone was run through the chromatographic-radio-autographic procedure indicated that even extremely minute amounts of material could be handled successfully by paper chromatography.

In order to test the procedure in a biological experiment, 250 microcuries of carrier-free I^{131} was administered intravenously to each of two normal adult rats. After 24–48 hours the rats were killed and the thyroids removed and hydrolysed with barium hydroxide in the manner usually employed in the determination of di-iodotyrosine and thyroxine. An aliquot of the neutral hydrolysate containing about 50 μgm. of total nitrogen was taken and run on a phenol/collidine two-dimensional paper chromatogram. A duplicate with added di-iodotyrosine, thyroxine and potassium iodide was treated similarly. A further chromatogram was run with only I^{131} present, as a control on the possible formation of iodinated compounds with the solvents. Similar runs were made on the one-dimensional paper strips, using various solvents. From each of the papers a radio-autograph was finally taken by placing the chromatogram, with only a sheet of 'Cellophane' intervening, against an X-ray film for up to seven days. The substances containing radio-iodine showed their presence on exposing the adjacent area of film. The papers were finally developed to show up the amino-acids and iodides. Ninhydrin was used for the former, and silver nitrate, followed by washing and exposure to light, for the latter. The added di-iodotyrosine and thyroxine could be readily picked out on the basis of their positions as determined from chromatograms of the pure compounds alone. It was an easy matter to determine, by superposition of the X-ray film on the developed chromatograms, the correspondence or otherwise between the spots on the film and those on the paper. Examples of the radio-autographs are shown in Figs. 1 and 2.

Fig. 1 is a radio-autograph of the two-dimensional chromatogram of hydrolysate of rat thyroid gland 48 hours after a tracer dose of I^{131}. The material was placed at the lower right corner. Phenol was first run from right to left and then collidine in an upward direction. The strong spot, marked 1 on the accompanying tracing, corresponded to the position of the bulk of the inorganic iodide; the weaker spot slightly above and to the left of it is usually seen and has not been identified. The thyroxine added to the hydrolysate as a marker went to the region of low radioactivity marked by the number 2, indicating that little, if any, radio-iodine was present in the thyroxine 48 hours after the iodine injection. The diffuse dark region to the left and above this is probably a solvent artefact, as it is also found when radio-iodide is run alone on the chromatograms. It corresponds also to the region where a visible yellow colour is formed from oxidation of the phenol used as the first solvent. The dark spot No. 3 corresponds exactly with di-iodotyrosine. Nos. 4, 5 and 6 are unknown I^{131}-containing substances. The two streaks, 7 and 8, have been constantly seen so far. It is difficult to understand what has produced them. They occur in the midst of the known amino-acids of the hydrolysate. All the well-defined radioactive spots are well clear of the positions of the common amino-acids. The rat killed after 24 hours gave similar results.

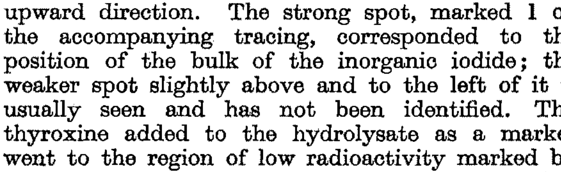

Fig. 2

Fig. 2 is a radio-autograph of two one-dimensional chromatograms. The upper one was run with phenol and the lower with collidine. The pinholes at the left indicate the starting point and those at the right the extent of the boundary travel. In each strip, 1 corresponds to the position of inorganic iodide, 2 to thyroxine, and 3 to di-iodotyrosine. It is seen that in collidine the thyroxine and the iodide run to the same position. The other bands are due to unknown substances.

The radio-autographs therefore indicate definite spots of radioactivity at the positions taken by inorganic iodide and di-iodotyrosine, little, if any, radioactivity at the spot corresponding to thyroxine, a diffuse background of radioactivity in one corner similar to that obtained from a chromatogram of a sample of the I^{131} injection solution alone, and several spots of radioactivity from unidentified substances. These unidentified spots have appeared consistently and in similar relative strengths in six two-dimensional chromatograms from the thyroid glands of the two rats. There can thus be little doubt that they represent chemical individuals, though whether they were originally present in the thyroid or were formed during subsequent treatment of the tissue has yet to be determined with certainty.

In any event the results obtained in this first experiment make it appear likely that with further improvements in technique a valuable new tool for the study of intermediary metabolism will be established. The final elucidation of the possible significance of these data with respect to thyroid physiology will probably require more work than we are in a position to undertake in the immediate future. It is for this reason, and with the hope that the technique may be of value to other investigators, that the results are being reported in the present incomplete form.

BRITISH SOCIAL HYGIENE COUNCIL

INTERNATIONAL SCHOOL IN SOCIAL BIOLOGY

THIS year the British Social Hygiene Council held its first international school in social biology at Berne, Switzerland, during August 21–September 4. The school was attended largely by teachers and welfare-workers, most of whom came from Great Britain, although a few from other nations gave enhanced interest to the proceedings. It was planned to be a blend of work and pleasure, the first week being devoted to regular lecture-sessions, and the second to excursions and personal recreation. The members were housed in groups in various hotels in Berne, while all meetings were held in the University buildings, where lecture-room accommodation had been placed at the Council's disposal free of cost.

The lectures and discussions were held in English. For the ordinary morning sessions the Council took out a staff from England; during the evenings the School had the privilege of hearing addresses by Swiss men of science and social workers. Prof. P. B. Medawar gave a series of lectures concerned with the principles of pure biology. In succession, he spoke on "Growth", "The Theory of Evolution from a Modern Standpoint", "Ageing in Individuals", and "Adaptation and Directive Behaviour". He was at pains to emphasize the comparative aspects of organic development, which he interpreted on modern genetical lines. Everyday problems of psychology at different stages in life were presented in four lectures by Dr. Mary Smith. Her subject-matter formed an integrated whole which served to give those who had had little previous experience of psychology a clearer understanding of its scope and method as well as insight into individual problems of their own.

Reflecting more directly the particular outlook of the British Social Hygiene Council, Mr. R. Weatherall spoke on "The Creative Mission of Social Biology", "The Human Family in a Changing Environment", "Some Implications of Modern Concepts of Race", and "The Human Aspects of Evolution". In choosing these subjects for his lectures his intention was to direct interest to broad problems of public concern in which social biology finds important applications which cannot be ignored. Further individual lectures were given by Miss M. M. West on "The Public Health Nurse and the Family Unit", and by Miss J. E. R. Kennedy on "The Police Court and the Community". Two informal Sunday meetings on the relationships between social biology and spiritual values led to a useful exchange of views, but served to show that on such a wide subject and without outside direction the method of open discussion does not take one very far.

Among the visiting speakers, the British Social Hygiene Council owes a special debt of gratitude to Dr. H. Revilliod for his invaluable help and advice. In his address on "Some Ways of Facing Social Evils in Switzerland" he explained how through careful organisation his country had been shielded from serious epidemics of infectious disease throughout all the disturbances of the war-time years. He referred to very satisfactory results now being obtained in the treatment of tuberculosis, and to the advantages of occupying the patients with gainful work. He also referred to the change in public attitude towards drunkenness in Switzerland, where even in the penal code it is recognized that heavy drinkers are sick members of society and in need of special care. His lecture ended with a description of the great success which has been attained in the prevention of endemic goitre by the addition of small amounts of potassium iodide to household salt. In earlier times the disease was very widespread in certain areas, giving rise to many cretinous and backward children, a number of whom were mute and deaf; now among young children it has disappeared.

Dr. St. Zurukzoglu contributed a paper on "Social Psycho-Hygiene". It was interesting to find that quite independently and through his own work he has arrived at a conception of social biology similar to that of the British Social Hygiene Council. In his view, organic factors, heredity, environmental influences and psychological dispositions were all contributory agents in the causation of disease. To cure the spiritually sick seemed to him as important as to heal the physically unwell, and he called for a medical pastoral service to work alongside that based on religion.

Dr. E. R. Frey of the Staatsanwalt gave a particularly stimulating address on "Biology and Juvenile Delinquency". Basing his argument on the theme that the treatment of juvenile delinquency is the foundation for all prevention of crime, he made it clear that only about 25 per cent of young offenders grow up into confirmed criminals. Members of this special group show serious abnormalities of a psychological nature and are often of low mental ability at the same time. As predisposing influences in the causation of crime, constitutional factors seem much more important than environmental conditions. The conclusion to which Dr. Frey's thesis led was that the treatment of young offenders should be based upon their biological circumstances and not upon the nature of their deed.

During the School, and in addition to excursions to some of the scenic attractions of Switzerland, visits were paid to certain departments of the hospital quarter at Berne, *Kindergarten* and other educational institutions, a housing estate, the international Pestalozzi school for refugee children at Trogen, the cantonal agricultural school at Rüti, and La Nuchtern, a home for the treatment of drunkards. Through the kind offices of Dr. V. J. Steiger, members of the

School were also able to see two films, the first dealing with the problem and treatment of drunkenness in Switzerland, and the second with the utilization of fruit, either in a fresh or preserved state, for human consumption or as a source of unfermented juices which can be made into most attractive drinks the popularity of which is increasing year by year.

R. WEATHERALL

CO-OPERATION IN BOTANICAL RESEARCH

FOR his presidential address to the Botanical Society of America (December 28, 1946), Dr. I. W. Bailey, chairman of the Institute for Research in Plant Morphology at Harvard University, selected the theme of "Co-operation Versus Isolation in Botanical Research" (*Chronica Botanica*, **11**, 1947).

In a world subject to profound and drastic changes, Dr. Bailey considers it inevitable that botanical science must also be affected, particularly the older branches of the subject. To quote his own words, he raises "the challenging question, what roles should taxonomy, anatomy, palæobotany and other phases of morphology be expected to play in future developments ?". A whole book could be devoted to the answer. Certainly the way has been prepared for a brisk and lively discussion.

"There are, of course, two extreme views regarding the matter. On the one hand, there are individuals who believe that these largely descriptive disciplines are moribund, if not actually over-ripe for interment, and that funds now dissipated for their support should be diverted into productive ultra-modern, experimental channels. On the other hand, there are those laissez-faire individuals who naively assume that civilization must continue to support their endeavours regardless of how unproductive their viewpoints and methodologies may have become.

"The latter individuals are living in a dream world of their own creation which is destined sooner or later to be rudely shattered. The former individuals fail to visualize the extreme complexity and variability of biological phenomena, and thus overlook or ignore numerous significant morphological variables in their experimental material."

In the first place, he asks if the extensive morphological researches of the last hundred years have not provided sufficient data to serve the purposes of contemporary and future experimental disciplines, in particular, those of the physiologist, the biochemist and the biophysicist. When these workers turn to the standard texts, can they find in them the information which they require ? Dr. Bailey replies in the negative, and in this he will be supported by most botanists who have given thought to the matter. Many of the supposedly fundamental ideas of plant anatomy are inadequate, based as they were on researches undertaken in relation to phylogenetic questions. An impartial consideration of almost any of the major problems of contemporary interest will reveal how much scope still remains for morphological inquiry. To quote Dr. Bailey : "It is evident that significant progress in the solution of important botanical problems is being retarded by inadequacies of existing morphological data and by the unquestioning acceptance of unreliable generalizations". He then asks how these difficulties are to be avoided in the future, and emphasizes the dangers and drawbacks of premature specialization in instruction and research. "This encystment of botany in specialized subdivisions encourages premature and excessive generalizations from limited induction and tends to inhibit unified attacks along broad fronts, such as are essential for the solution of the more complex and difficult types of botanical problems." The solution of any of the major problems of biology requires the close co-operation of workers in different fields and a harmonizing of the data of the several contributory disciplines. Various means are available whereby co-operation can be encouraged, but as to how the latter aim is to be achieved Dr. Bailey is rather less specific. The magnitude of the task is oppressive : in practice it will call for the sustained activities of a team of workers. Yet, as experience teaches, major biological syntheses depend on the special qualities and capacities of particular individuals, and these, apparently, are of rare and sporadic occurrence.

Morphologists, whether adherents of old or new conceptions, are not alone in being scourged by Dr. Bailey. "If one probes deeply into the applications of physics and chemistry in the analysis of plant materials one likewise finds evidences of premature and excessive generalization from restricted viewpoints. I have encountered this tendency in exaggerated form in chemical analysis of plant tissues and particularly in physical and chemical investigations of the walls of plant cells. The specialist in specific physical and chemical methodologies is likely to run astray unless his deductions are verified by individuals who are thoroughly familiar with the full complex of structural variables in a wide range of plants."

But Dr. Bailey is by no means pessimistic in his outlook for plant morphology. He views with confidence a future in which taxonomy, anatomy and other morphological disciplines will be stimulated and broadened by close contact with one another and with other branches of the science. The result should be a closer approach to the solution of the central problems of biology. "To facilitate such mutually beneficial relationships, it is essential to break down existing emotional and intellectual barriers." The morphologist must recognize the limitations of his own techniques and appreciate the assistance which other disciplines can afford him in solving problems in his own particular field. "He must acquire sufficient familiarity with chemistry and physics to enable him to talk intelligently with workers in other disciplines." In emphasizing this point, Dr. Bailey's observations are no doubt pertinent in relation to some of the research institutions in the United States : in a majority of British universities, a reasonable knowledge of chemistry and physics is now regarded as an essential preparation for botanical studies.

A particular interest is attached to that section of the address in which Dr. Bailey attempts to show how co-operation between the different subdivisions of botany is to be achieved. "It cannot be coerced or developed directly by administrative fiat. It must arise naturally and more or less spontaneously or not at all. The wisest and most effective procedure should be to create a general environment that encourages rather than inhibits co-operative efforts." To some extent this can be achieved by wise administration, particularly by making suitable appointments and the judicious allocation of funds. An allocation of funds which tends to encourage excessive diversification and specialization and which favours "unbridled individualism" is to be deplored. "Such policies may yield spectacular and highly significant results during the pioneering stages of a new trend of specialization, but frequently leave a large residue of injurious consequences, and do not create a general environment favourable for co-operative endeavours. I do not imply by this that one should make a fetish of team-play or that the lone wolf and the prima donna should be eliminated and replaced by amiable mediocrities, but rather that the training of graduate students should be broadened and that where individuals of recognized ability wish to co-operate in research, funds to encourage such relationships should be available. . . . We must now strive in botany as in national affairs to prevent a reversion to isolation and to intellectual encystment."

Even in the larger universities in the United States it is not anticipated that extensive schools of research in all the subdivisions of botany can be supported. Dr. Bailey advocates that each university department should develop strength in particular directions and that students should be free to move from one university or institution to another according to their special interests.

In concluding, Dr. Bailey considers how the funds available for botanical research can best be used. One of the methods commonly adopted is to give handsome support to one or two leading individuals who have established a reputation in a particular field. This he regards as possibly the easiest and least expensive way for some institutions; it may even be the easiest and least expensive way of advancing the frontiers of science. But other possibilities should not be overlooked. Policies of the kind mentioned above commonly lead to narrow specialization and they "tend to inhibit attacks upon major biological problems which require the concatenated efforts of different disciplines for their solution". In their more exaggerated forms, they may in time create such a complex of competitive subdivisions as to render impossible the integration of the data of the several branches. Botanical science must inevitably suffer from the attendant disruption.

C. W. WARDLAW

FORMULÆ AND BRAIN WEIGHTS

PROF. E. W. COUNT[1] has recently examined the various formulæ which have been suggested for expressing the relationship between brain-weight and body-weight in vertebrates, and has also introduced a new formula. In his extensive study he states that his objects are: "(1) to formulate the growth behaviour between brain and body weights in human ontogeny, (2) to find any traits in common with other Primates and Mammalia, (3) to formulate analogous behaviour in comparative anatomy; and (4) to search for any connexions between ontogeny and comparative anatomy". His paper is divided into five sections: (1) is introductory, discussing method and terminology; (2) deals with the data and formulæ from the point of view of ontogeny; (3) discusses the comparative anatomy problem, includes an extensive criticism of previous work and introduces the author's new formula; (4) attempts to relate the ontogenetic results to the phylogenetic; and (5) is a summary. The paper concludes with an extensive bibliography and a number of tables of data.

If we denote brain-weight by y, body-weight by x, and parameters by a, b, c, Prof. Count's main conclusions appear to be as follows:

(*a*) Ontogenetically, in both fœtal and post-infantile stages, the relationship $y = ax^b$ will hold.

(*b*) Phylogenetically, for mammals the relationship is, $y \doteq ae^{bx-cx^2}$; for reptiles $y = ae^{bx+cx^2}$. The form $\log y = \log a + b \log x \pm c (\log x)^2$ is termed the 'cephalization function'.

(*c*) If the intersection of the reptilian cephalization exponent with the general mammalian exponent is taken as a new origin, then the mammalian exponent may be considered as a transformation of the reptilian.

(*d*) Increase in absolute body-size is requisite for higher cephalization. This latter term is nowhere clearly defined, but appears to be related to some concept of more complicated structure and function.

Prof. Count's discussion of the data and their sources is full and most welcome; he not only supplies the reader with lists of some of the available data, but also includes tables in which these data are collected. Unfortunately, many of these figures are mean-values and consequently of considerably less value than the individual observations. For some reason Dr. H. B. Latimer's excellent data on cats are not included, and are considered to be "*too* good"; no reason for such a rejection is given.

Snell[2] was first to suggest the use of the formula $y = ax^b$, and the adoption and development of this formula for brain/body weights by Dubois, Lapicque and Brummelkamp is well known. These authors have maintained that the value of the parameter b is $0{\cdot}56$ for different but related species of vertebrates, but is $0{\cdot}26$ for animals of different sizes but belonging to the same species. Brummelkamp, moreover, has stated that the values of $\log a$ are always integral multiples of $\sqrt{2}$. Count discusses this work in considerable detail and rightly concludes that these suggested values for the parameters have no adequate foundation. This work has already been criticized by v. Bonin, who has treated the data from a different point of view and fits a straight line to the logarithms of the body-weights and brain-weights of mammals, concluding that the value of b was $0{\cdot}655$ while the value of a varies from species to species. Count's objection to v. Bonin's treatment seems to be mainly subjective; he thinks that mammals form too large a group, and considers that if two animals have the same body-weight, the one with the larger brain will be the more intelligent. The method of v. Bonin does not lead to this conclusion.

Many of these criticisms are well founded, especially those directed against the Dubois–Lapicque–Brummelkamp school, but other equally radical criticisms may be made which would also apply to Count's own treatment—the mathematical treatment is quite inadequate.

If it is decided to fit a curve $y = f(x, a, b, c \ldots)$, where x is the independent variable and a, b, c are parameters, it is necessary to make certain assumptions about the distribution of the variables. If we fit by the method of least squares, we usually assume that the x's are free from error and the y's are normally distributed; the values of the parameters and their standard errors can then often be estimated. The authors discussed by Count, and Count himself, assume that the results of fitting

$$y = ax^b \text{ and } \log y = \log a + b \log x$$

will be the same. This is not the case, since we assume y to be normally distributed with x free from error in the first case, whereas in the second case log y is assumed to be normally distributed with log x free from error. If y is normally distributed, the distribution of log y will not be normal, and conversely. This point has been briefly discussed elsewhere[3]. Presumably, Count has assumed a log normal distribution, but he has not estimated the standard errors of the parameters and consequently comparisons between their values are impossible. Furthermore, his curves have been fitted to mean values of groups; this leads to further difficulties which are not mentioned, and it would appear that mean values have been treated as if they were actually observations.

It is not clear why the particular form $\log y = \log a + b \log x - c (\log x)^2$ should have been chosen as giving the best description of the data. A number of formulæ is listed (p. 1,034), and the author states that these are "less satisfactory". No indication of a criterion for this judgment is given, but it would appear that it was merely subjective ("It seems a very fair fit", p. 1,042). In fact, although the author prefers his formula to the allometric form, he nowhere shows that his formula does, in fact, give a closer fit: since he introduces an extra parameter, it probably does.

Count also criticizes previous workers for allowing their personal views to influence their choice of data, but he does not appear to be free from this reproach himself; for example, he omits the Cynocephali from the Cercopithecidæ "because of their obviously high specialization" (p. 1,035). His omission of Dr. Latimer's data has been noted already.

No theoretical justification is given for the new formula and no biological interpretation of the parameters is suggested. If it were possible to find a theoretical basis for this formula, one would find it of greater interest; but the author says that it is frankly empirical and offers no hope of any such justification. The analogy which is drawn between the cephalization exponent and the path of a projectile is quite unconvincing.

The paper is not easy to read. The author speaks of "complex exponents in place of the b": presumably he means that b may be a real function of x and not merely a number. The adjective 'statistical' is used where the author seems to mean 'numerical'. The sentence (p. 1,055) "This apparent fact may be important, evolutionally: for good results in geometric statistics, it is vitiating" is incomprehensible. Many other examples could be quoted.

Prof. Count has provided a valuable summary of the data relating to his subject, and his criticisms and speculations are interesting. Unfortunately, he has failed to apply modern statistical methods and to appreciate the limited value of empirical formulæ. Any such formulæ would imply that the increasing complexity of the brain, both in structure and function, which is found in vertebrate phylogeny, can be analysed in terms of its weight and that of the body of the animal. It is doubtful if this is possible since, although the physiological unit of neural activity may be the same throughout the vertebrate system, it would appear that the anatomical patterns formed by these units increase in complexity and not merely in size. For example, the optic tecta of Amphibia and Reptilia have different structural patterns, and the thalamus of Reptilia has a different pattern from that of rodents and so on. Even for these two structures the analysis must go deeper; *a fortiori* it would seem that mere weight is far too superficial a unit for the analysis of the total brain.

In order to make a mathematical analysis of brain organisation, either in ontogeny or phylogeny, the physiological patterns and their correlated anatomical structures need deeper quantitative investigation. It may then be possible to form a mathematical model which will enable us not only to picture our present knowledge concisely, but also will suggest directions for future research.

RUTHERFORD CELEBRATIONS IN PARIS

ON November 7 and 8, in Paris, the World Federation of Scientific Workers, the president of which is Prof. F. Joliot-Curie, held a solemn commemoration of the tenth anniversary of the death of Lord Rutherford. This graceful and extremely successful tribute by scientific men from all parts of the world emphasized the international character of science and the deep regard and lively admiration of men from twenty nations for the work and personal qualities of the greatest of contemporary British scientists. The presence of Lady Rutherford, and of two of her grandchildren, gave a personal character to the ceremony which a purely scientific gathering would have lacked.

The conference proper began with a reception by the President of the French Republic in the afternoon of November 7 at the Élysée Palace, at which guests were received by the President and Mme. Auriol. The Premier and members of the Cabinet were present. M. Auriol spoke of the work of Rutherford and of the international character of science, and expressed optimism that the fruits of his genius and of science in general would be used for the good of mankind. Prof. F. Joliot-Curie responded. The grandeur of the Palace, the magnificence of this tribute by the French nation through its President, and the charm of our hosts, made a deep impression upon all, and especially upon the British delegates.

In the evening at 9 p.m. a solemn commemoration was held in the Great Hall of the Sorbonne. The French Foreign Minister, M. Bidault, was in the chair and the hall was crowded with more than two thousand people, including diplomatic representatives of many countries. Tributes were paid by Prof. Niels Bohr (Denmark), whose message was read by Dr. Møller, by M. de Broglie (France), Prof. M. L. Oliphant (Great Britain), Prof. Harold Urey (United States), and Prof. Joliot-Curie (president of the World Federation of Scientific Workers). A large illuminated photograph of Rutherford hung over the stage, an orchestra played before the proceedings began and between the speeches, and the recorded voice of Rutherford was heard through the loud-speaker system. This was a most solemn and moving occasion.

On the morning of November 8 further tributes were paid in the lecture theatre of the Collège de France by Prof. M. N. Saha (India), Sir George Thomson (Great Britain), Prof. J. S. Foster (Canada) and Mme. Irène Joliot-Curie (France). M. Louis de Broglie was in the chair. It is understood that all speeches will be published in French. Advantage was taken of the character of the gathering to hold a discussion on the international and social implications of modern science, a subject dominated at the present time by atomic energy, the practical fruit of the scientific labours of Rutherford and his colleagues throughout the world.

There was a reception at the Maison de la Pensée Française and a lecture on "The Function of International Science in the Solution of the Economic Problems of To-day" delivered in French by Prof. J. D. Bernal.

It was particularly fitting that these celebrations should have been held in France, where Becquerel and the Curies laid the foundation of nuclear physics by their pioneering discoveries in radioactivity, and especially that the daughter and son-in-law of the Curies should have been largely responsible for the conception and organisation of the conference. Those of us who were students and colleagues of Rutherford found the proceedings in every way appropriate, magnificent in conception and strangely moving. This spontaneous tribute to the genius and lovable personality of Rutherford merits the gratitude of all Britons.

The organisation of the commemoration was in the hands of a committee of the World Federation of Scientific Workers, and its great success was due largely to the generous hospitality of the French Government and its full participation in the proceedings. The United Nations Educational, Scientific and Cultural Organisation recognized the unique significance of the occasion by providing funds to cover the travelling expenses of many who attended.

M. L. Oliphant

CULTIVATION OF THE CRICKET BAT WILLOW

In Forestry Commission Bulletin No. 17 (London: H.M. Stationery Office, 1946) the cultivation of the cricket bat willow is described. The tree willows are divided into two groups. In the first, the trees are pollarded and yield small produce such as stakes and poles, the latter used for hurdles and rough fencing. In the second group, timber of larger size is produced which may be used, as in some parts of the Midlands, for making field gates, but of which the best known and most important manufactured product is the cricket bat. Pollarded willows are very characteristic sights in many parts of England as, for example, in the valley of the Thames; Somersetshire marshes; the levels of the Bedfordshire Ouse, and along many of the small streams in southern England. In most cases the agricultural population know well how to deal with this type of tree, the numbers of which do not appear to diminish in the parts of the country where they are found, and their produce furnishes a very useful source of certain types of woody material in use by the agricultural community.

When the object is to produce material of timber size, the areas devoted to willow must be treated on a more intensive forestry method, and this applies to a very high degree in the case of trees from which it is desired to obtain timber for the manufacture of cricket bats. With this object in view the willow must be selected with very great care so far as the willow stock is concerned, and to-day, for the purpose in question, it has led to an ever-increasing demand for *Salix alba* var. *cærulea*. The demand for this variety has been a matter of gradual development, and the methods of its cultivation have been carefully improved, based on trial and error with reference to methods of propagation and planting.

In the past, a number of private owners have tried to undertake the production of this high-quality willow timber, with the object of selling it as material for cricket bat production, and considerable failures have resulted. It is not that the cultivation of the willow itself is actually difficult, but a great deal of close attention is necessary, and more especially during its early life, and the right variety must be obtained at the start. It is for this reason that the Forestry Commission has had drawn up and issued this bulletin on the cultivation of this valuable product. The subject is dealt with under situation, climate, soils, propagation (by various methods), planting and tending the trees; also the various types of possible damage are discussed; the character and uses of willow timber, and finally the systematy of the cricket bat willow and its allies. In fact, the bulletin may be considered to be an up-to-date guide to any who wish to take up this interesting branch of economic tree-growing. There is also a number of plates illustrating the text.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Saturday, December 6

North of England Institute of Mining and Mechanical Engineers (at Neville Hall, Newcastle-upon-Tyne), at 2.30 p.m.—Mr. Donald Hindson, Jr.: "Some Aspects of Dutch Coal Mining".

Monday, December 8

Chemical Society (in the Main Chemistry Lecture Theatre, The University, Edgbaston, Birmingham), at 4.30 p.m.—Dr. W. A. Waters: "Mechanisms of Oxidation".

Institution of the Rubber Industry, Midland Section (at the James Watt Memorial Institute, Great Charles Street, Birmingham), at 7.15 p.m.—Dr. D. Parkinson: "Newer Developments in Carbon Black".

Tuesday, December 9

Zoological Society of London (at Regent's Park, London, N.W.8), at 5 p.m.—Scientific Papers.

Institution of Chemical Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. N. H. Pratt: "The Heat Transfer in a Reaction Tank Cooled by Means of a Coil".

Institution of Electrical Engineers, Radio Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. B. E. G. Mittell: "Commercial Disc Recording and Processing".

Illuminating Engineering Society (at the E.L.M.A. Lighting Service Bureau, 2 Savoy Hill, London, W.C.2), at 6 p.m.—Dr. J. H. Nelson: "Decoration and Industrial Lighting".

Royal Institute of Chemistry, London and South-Eastern Counties Section (in the Material Research Laboratory, Philips Lamps, Ltd., New Road, Mitcham Junction), at 7.15 p.m.—Mr. C. G. A. Hill, assisted by colleagues: "Luminescent Materials—their Properties and Uses", with demonstrations.

Wednesday, December 10

Institute of Fuel, North-Western Section (at the Engineers' Club, Albert Square, Manchester), at 2 p.m.—Mr. S. W. Bertenshaw: "Oil Firing Practice".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Mr. Michael Graham: "Science and the Fishing Industry".

Geological Society (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

Institution of Electrical Engineers, Transmission Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. H. Hurworth: "Some Observations on Oil Deterioration in Transformers and Switchgear"; Mr. J. S. Forrest: "An Electrical Resistance Test for Insulating Oils".

Manchester Literary and Philosophical Society, Social Philosophy Section (at the Portico Library, 57 Mosley Street, Manchester), at 5.30 p.m.—Lecture by Miss C. V. Wedgwood.*

Society of Chemical Industry, Nutrition Panel of the Food Group (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—"Organoleptic Tests in the Food Industry".

Manchester Metallurgical Society (at the Engineers' Club, Albert Square, Manchester), at 6.30 p.m.—Mr. Ivor Jenkins: "Controlled Atmospheres for Heat Treatment of Metals".

Institution of the Rubber Industry, Preston Section (at the Victoria and Station Hotel, Preston), at 7 p.m.—Mr. H. Jackson: "The Nature and Reason for Ingredients in Rubber Mixings".

Institution of Structural Engineers, Lancashire and Cheshire Branch (at the College of Technology, Manchester), at 7 p.m.—Mr. T. H. Carr: "Civil Engineering, with particular reference to Structural Work for Power Stations".

Institute of Welding, North London Branch (at East Ham Technical College, Barking Road, London, E.6), at 7.30 p.m.—Mr. C. E. Slade: "Developments in Resistance Welding".

Society of Dyers and Colourists, Northern Ireland Section (at the Queen's Hotel, Belfast), at 7.30 p.m.—Mr. J. Boulton: "What Research has Meant to the Practical Dyer and What it will Mean".

Thursday, December 11

Chemical Society (in the Chemistry Lecture Theatre, The University, Liverpool), at 4.30 p.m.—Prof. F. G. Young: "Hormones and Enzyme Action".

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Discussion on "The Physiology of Resistance to Disease in Plants" (to be opened by Prof. W. Brown, F.R.S.).

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Scientific Papers.

Institution of Electrical Engineers, Installations Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. R. Allan: "Electrical Engineering Problems in the Tropics".

Institution of Civil Engineers, North-Western Association (at the Engineers' Club, Albert Square, Manchester), at 6.30 p.m.—Mr. T. K. George and Mr. K. B. Manyam: "The Rational Design of Settlement Tanks".

Royal Photographic Society, Scientific and Technical Group (at 16 Prince's Gate, London, S.W.7), at 7 p.m.—Mr. G. B. McAlpine: "Photography of Small Objects for Reproduction".

Women's Engineering Society (at 35 Grosvenor Place, London, S.W.1), at 7 p.m.—Mr. C. Cropper and Mr. G. M. Wells: "Ultrasonics".

Society of Dyers and Colourists, West Riding Section (at the Great Northern Victoria Hotel, Bradford), at 7.15 p.m.—Dr. R. L. Elliott: "Dyeing and Finishing from the Consumer Angle".

Chemical Society, Society of Chemical Industry, and Royal Institute of Chemistry, Edinburgh and East of Scotland Sections (at the North British Station Hotel, Edinburgh), at 7.30 p.m.—Dr. G. Roche Lynch: "Medico-Legal Experiences".

Pharmaceutical Society (at 17 Bloomsbury Square, London, W.C.1), at 7.30 p.m.—Dr. Adrien Albert: "Modern Knowledge of Protein Structure and its Pharmaceutical Significance".

Royal Institute of Chemistry, London and South-Eastern Counties Section (at Acton Technical College, High Street, Acton, London, W.3), at 7.30 p.m.—Dr. H. Baines: "The Chemist in the Photographic Industry".

Pharmaceutical Society, Manchester, Salford and District Branch (at the Midland Hotel, Manchester), at 7.45 p.m.—Mr. H. N. Linstead: "Pharmacy under the National Health Service".

Friday, December 12

Textile Institute (at 16 St. Mary's Parsonage, Manchester), at 1 p.m.—Mr. F. Heywood: "Textile Machinery Development and Research".

Association of Applied Biologists (in the Surveying Lecture Theatre, Royal School of Mines, South Kensington, London, S.W.7), at 11 a.m.—Dr. E. S. Bunting: "Oil Seed Crops"; Dr. K. Holly: "Control of Weeds in Oil Seed Crops"; at 2.15 p.m. (in the Mathematics Lecture Theatre, Huxley Building, Royal College of Science)—Dr. S. G. Jary: "Insect Pests of Brassica Seed Crops"; Dr. J. R. Busvine: "The Mosquito Eradication Campaign in Sardinia".

Physical Society, Optical Group (joint meeting with the Industrial Spectroscopic Group of the Institute of Physics, in the Physics Department, Imperial College of Science, Imperial Institute Road, London, S.W.7), at 3.30 p.m.—Demonstrations and Paper.

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Scientific Papers.

Institution of Electrical Engineers, Measurements Section (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. R. Poole: "The Design, Testing and Calibration of a Combustible-Gas Detector".

Institution of Mechanical Engineers, Applied Mechanics Group (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Papers on "Photo-Elasticity". Mr. W. A. P. Fisher: "Basic Physical Properties relied on in the Frozen Stress Technique"; Mr. R. B. Heywood: "Modern Applications of Photo-Elasticity".

Institution of Electronics, North-Western Branch (in the Reynolds Hall, College of Technology, Manchester), at 6.30 p.m.—Prof. R. E. Peierls, F.R.S.: "The Electron and other Constituents of Matter".

Oil and Colour Chemists' Association, Manchester Section (at the Engineers' Club, Albert Square, Manchester), at 6.30 p.m.—Educational Films: (*a*) "Flame Cleaning of Structures prior to Painting"; (*b*) "Spray Painting Technique" (Commentary by Mr. F. G. Dunkley).

Plastics Institute (at the Engineers' Club, Albert Square, Manchester), at 6.45 p.m.—Mr. H. R. Poole: "Silicone Resins".

Institute of Economic Engineering (at Cowdray Hall, Henrietta Place, London, W.1), at 7 p.m.—Miss Patricia Elton Mayo: "The Consultant's Approach".

Paper Makers' Association (Technical Division), Northern Division (at the Engineers' Club, Albert Square, Manchester), at 7 p.m.—Mr. B. Dixon and Mr. W. J. Binns: "Some Modern Developments in Paper-making Machinery".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. H. Munro Fox, F.R.S.: "Red, Green and Blue Blood"

Saturday, December 13

Biochemical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 11 a.m.—Symposium on "The Biochemical Reactions of Chemical Warfare Agents".

British Psychological Society (in the Hastings Hall, Tavistock House, Tavistock Square, London, W.C.1), at 2.30 p.m.—Mr. W. R. Geddes: "Incentives in a Changing Native Culture".

Institution of Chemical Engineers, North-Western Branch (in the Reynolds Hall, College of Technology, Manchester), at 3 p.m.—Mr. C. Toyne: "Heat Transfer in Agitated Pans".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Physics at the University of Otago, Dunedin—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (December 15).

Assistant Chemist in the Plant Protective Chemistry Section—The Secretary, East Malling Research Station, East Malling, Maidstone, Kent (December 15).

Professor of Dental Prosthetics in the King Edward VII College of Medicine, Singapore—The Secretary, Inter-University Council for Higher Education in the Colonies, 8 Park Street, London, W.1 (December 31).

University Demonstrators (2) in the Department of Geography—The Secretary, Appointments Committee of the Faculty of Geography and Geology, Department of Geography, Downing Place, Cambridge (December 31).

Lecturer in Anatomy to teach histology and embryology, a Senior Lecturer in Agriculture, and a Reader in Agriculture, at Makerere College, Uganda—The Secretary, Inter-University Council for Higher Education in the Colonies, 8 Park Street, London, W.1 (December 31).

Senior Lecturer or Lecturer in Physics at Natal University College, Pietermaritzburg—The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (December 31).

Director, and Assistant Scientific Officers (3), at the Poultry Research Station—The Scientific Director, Veterinary Educational Trust, 232–235 Abbey House, Victoria Street, London, S.W.1 (December 31).

Chair of Philosophy at King's College, Newcastle-upon-Tyne—The Registrar, University Office, 46 North Bailey, Durham (December 31).

Headships of the Departments of Botany, Zoology, Physiology, Anatomy, Pathology, Medicine, Surgery, and Public Health, at Ibadan College, Nigeria—The Secretary, Inter-University Council for Higher Education in the Colonies, 8 Park Street, London, W.1 (January 1).

Lecturers (2) in Chemical Engineering—The Secretary, The University, Edmund Street, Birmingham 3 (January 1).

Superintendent in the Ship Division of the National Physical Laboratory—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2065 (January 7).

Senior Principal Scientific Officer in the Telecommunications Research Establishment of the Ministry of Supply at Malvern—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2066 (January 7).

Ecologist in the Tsetse Control Department of the Government of Uganda—The Director of Recruitment, Colonial Service, 15 Victoria Street, London, S.W.1.

General Farm Manager at the Livestock Research Centre—The Scientific Director, Veterinary Educational Trust, 232–235 Abbey House, Victoria Street, London, S.W.1.

Professor of Pharmacology by the Government of Iraq for the Royal College of Medicine, Baghdad—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.N.18525.

Expert in Agricultural Extension and Demonstration Work by the Government of Iraq for the Directorate-General of Agriculture—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.N.18179.

Entomologist by the Government of Iraq for work in the Plant Protection Division of the Directorate-General of Agriculture—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.N.18155.

LAND UTILIZATION IN BRITAIN

FOR well over a year public concern regarding the utilization of land in Great Britain has found repeated expression, more especially regarding the claims of the Services, but also those of the Ministry of Fuel and Power and of the various municipalities in connexion with water, power or other schemes. During 1947, in addition to the Town and Country Planning Act, which did nothing to allay concern regarding departmental claims and activities, there have been published the reports of the Hobhouse Committee on National Parks in England and Wales, the Huxley Committee on the Conservation of Nature in England and Wales, the Hobhouse Committee on Footpaths and Access to the Countryside and the Scottish National Parks Committee, under the chairmanship of Sir J. Douglas Ramsay, on National Parks and the Conservation of Nature in Scotland, as well as, more recently, that of the New Forest Committee under Mr. H. T. Baker. All these reports contain much common ground in regard to the dangers of conflict between departmental and national interest, and represent a large measure of consensus of opinion that is both responsible and authoritative.

There are as yet few, if any, signs of a disposition on the part of the Government to deal with the central issues, and to give attention to such important representations and recommendations. The official committees in the reports noted above have shown good cause for reserving for national parks about 5,680 square miles in England and Wales, and 2,000 square miles in Scotland, together with fifty-two conservation areas in England and Wales, amounting to 70,000 acres, and further conservation areas in Scotland which have yet to be specified. According to a statement by Mr. M. V. Osmond, assistant secretary of the Council for the Preservation of Rural England, at a conference in London on November 26, the total Service requirements for training areas and ranges amount to about 1,328 square miles. Of these, only 156 square miles are in Scotland, and no less than 255 square miles claimed by the Services lie in the proposed national park areas of England and Wales. Responsible leaders of the rural preservation movement clearly appreciate the reasons for the larger requirements of the Services. These needs will not be recognized as widely and as fully as they deserve, however, until the Government has made available the promised general picture of the land requirements of the Services and a statement of the principles determining the choice of sites. While choice appears to be piecemeal, there will persist the tendency, however unfounded, to regard the Services as unimaginative enemies of agriculture, amenities, archæology and the study of Nature, and resentment at departments which appear to be judges in their own cause will grow.

There is already too much evidence of the latter tendency in this as in other matters for it to be disregarded lightly by the Government, all the more because a clear lead to the decisive principles has been given by the reports already noted. The

Hobhouse Committee, in its report on national parks, in recommending that the prime charge of national parks should be given to a specific central authority, under the parliamentary responsibility of the Minister of Town and Country Planning, recognized that farming and essential rural industries must flourish unhampered by unnecessary controls or restrictions, and protected so far as possible from the inconveniences that might arise from an increased number of visitors. Other forms of large-scale development and land use, which might affect adversely natural beauty and popular enjoyment, such as water catchment, mineral extraction, military training and commercial forestry, should be accommodated in national parks only under proved national necessity, and even then the greatest care should be taken to minimize their detriment to the landscape.

To that statement no exception can be taken, nor to the Committee's reiteration that the administration of a national park must be for the benefit of the nation and by appropriate national decision and action. The doubts arise rather as to whether, under the parliamentary responsibility of the Ministry of Town and Country Planning, a national parks commission can achieve its planning objectives in the control of the use of such areas. However successful the commission may be in recruiting staff of the character and ability essential, it will need much more powerful backing than the present Ministry of Town and Country Planning has been able to offer in order to resolve the conflicts between national and local interests which may arise in some industrial development or extension of public utilities, and particularly to resist dangerous encroachments of other departments of State. The Committee itself recognizes that the major threats in the type of country envisaged for national parks arise from the activities of Government departments, and it suggests the establishment of a permanent Cabinet or ministerial committee charged with the reconciliation of all claims to the use of land by Government departments, wherever conflicts of interest prove insoluble by the ordinary means of inter-departmental consultation. That may indeed provide a solution, but only if more is done beforehand. The Minister of Defence should at least be responsible for seeing that the demands of Service departments for land are sifted and co-ordinated before they are submitted to any inter-departmental committee; and there must be an end to the practice of departmental requirements for land being formulated without reference to the Ministry of Town and Country Planning.

The Huxley Committee, in its report on the Conservation of Nature in England and Wales, was even more explicit. Within certain designated areas it recommended that further development or economic exploitation should not be begun, nor military occupation planned, before the appropriate scientific authority has been informed and given the opportunity of bringing objections before an impartial tribunal. The Committee does not claim that in these areas scientific considerations should have an overriding voice, but merely that they should be recognized as one of the interests that must be taken into account before final decisions are made upon proposals that are likely to have drastic effects upon prevailing conditions; and it points out rightly that machinery for the resolution of conflicting interests at whatever level can only be effective if the positive claim for scientific consultation in such areas is fully recognized.

It has been the Government's apparent disregard of so reasonable a claim that is responsible for much of the concern with which the question of Service lands is at present regarded. The Huxley Committee proposed that as a matter of urgency the Ministry of Town and Country Planning should communicate to all departments and public authorities concerned the list of sites recommended for preservation and should take steps to ensure that no changes in land use (or extensions of temporary war-time uses) affecting these areas should be sanctioned without the fullest investigation of their possible repercussions on Nature conservation.

The Hobhouse Committee on Footpaths and Access to the Countryside was likewise impressed with the urgency of the situation and the dangers attendant on delay. In particular, its recommendations regarding long-distance rights of way, such as the Pennine Way recommended in the Scott Report, are endangered by some of the recent claims of the Services; and the survey which it recommends should clearly be undertaken as a matter of urgency by the Ministry of Town and Country Planning. Once again, observations on conflicting interests in land are eminently reasonable; indeed, they may well be held to concede too much to water undertakings, the Forestry Commission and other special interests. It will be noted that the Committee firmly recommends that public access should be secured over all training grounds except where live ammunition is used, and that local permission should also be granted, where practicable, for public access over artillery ranges when firing is not in progress. Moreover, once again attention is directed to the necessity of arrangements to ensure that planning authorities have full opportunity of making representations, and, if desired, of being heard in regard to the effect of Service departments' proposals on public access.

The Hobhouse Committee in its report estimates the area of land required by the Service departments for training purposes in England and Wales as in the neighbourhood of a million acres, mostly uncultivated land and including much of the finest country for rambling access. Whether or not it is due to the lesser demands on such areas in Scotland, the Scottish National Parks Committee and the Scottish Wild Life Conservation Committee are much less forthright. They assume, rather than recommend, that the Secretary of State for Scotland is competent to ensure that other Government departments will consult him, as planning minister for Scotland, about any proposals of their own for development, and that it will be the normal practice for him to consult any national parks commission and park planning committee before giving any decision. They recommend, indeed, that national park areas should be treated as particular areas in which statutory undertakings are not exempt from planning control, and that it should be obligatory on such undertakings and on Government departments to consult the national parks commission before giving approval to any development proposed in such areas. The assumption that land in such areas owned by Government departments, local authorities and statutory undertakings will be developed and administered in conformity with national park requirements, to say the least, is a little naïve and scarcely accords with recent experience.

The ideas and recommendations of these two Committees are in line with those of the National Parks Committee for England and Wales, and include the provision of the long-distance paths and of public access to all uncultivated land in a national park area, subject to suitable regulations. On water catchment areas, indeed, the Committees are disposed to be less lenient to the water undertakings than is the Hobhouse Committee. Finally, it may be noted that the New Forest Committee in its report urges that all war-time encroachments which are such a serious feature in the present condition of the Forest, including the bombing ranges, the aerodromes, the War Agricultural Executive Committee's cultivations, and a prisoner-of-war camp and stores depot, should cease at the earliest possible moment and the lands affected should be restored to their former state. Further, to ensure that scientific interests are not adversely affected by drainage, burning plantations or other changes, the whole Forest, open and enclosed, should be declared a Nature reserve.

The relevance of this particular report, apart from the similarity in its general trend, lies in the illustration it affords of the imperative necessity of immediate action to safeguard areas and amenities, some of which are unique in Britain and many of which are threatened from several quarters. It is pertinent to remind the Government that good intentions are no substitution for sound judgment and wise administration; it is also true that the feeling of frustration and exasperation which so many piecemeal proposals are engendering and spreading, in the absence of any indication of some governing policy and some overriding authority competent to resolve issues in the national interest are, like other factors in the general situation, undermining the incentive to work. The case for national parks rests at least in part on the stimulus to health which free access to unspoilt natural beauty can afford. Already measures which, on the plea of the economic crisis, the Government has imposed, have restricted the means and freedom of access to the countryside for many thousands of workers in the industrial towns of Britain. The Government has rightly called for increased effort and for longer hours of work at the present time; it cannot wisely ignore the importance of providing as fully as possible the means for enjoying those types of recreation which in a war-weary and increasingly drab and regulated world can bring spiritual as well as physical healing to jaded minds and bodies.

This aspect was strongly urged by Mr. Edward Evans in relation to the Norfolk and Suffolk Broads in a debate on the adjournment in the House of Commons on November 25. He pleaded with the Minister of Town and Country Planning to restore to the public the rights of access which were being impeded by private interests as well as by local authorities, and for measures to deal effectively with the growth of weeds and other aquatic vegetation. Mr. Evans made it clear how grave are the consequences of neglect to deal with such insidious encroachments and how important is the time factor. The Broads are one of the areas recommended for inclusion in the national parks scheme, and although the Minister of Town and Country Planning indicated that his Ministry agreed in general with the recommendations of the Broads Preservation Committee and promised a definite reply later to the points raised, the terms of his reply at least implied some doubt as to the Government's readiness to undertake legislation on the report of the National Parks Commission. If such legislation was undertaken, however, he committed the Government to the inclusion of the Broads as one of the national park areas.

Much the same arguments were urged by Mr. S. Swingler on the following day in regard to the requisitioning of parts of Cannock Chase and the question of public access to that area, 24,000 acres of which are scheduled as a conservation area for wild life. Mr. S. Swingler pointed out that while a large part of this relatively unspoiled countryside had for some time been maintained by the Forestry Commission, 1,000 acres are still retained by the Service departments and public access is denied to a much larger area. It had recently been disclosed that the Services had claims on nearly 2,000 out of the 30,000 acres; all that Mr. Swingler said about the importance of public access for the surrounding large urban areas was strongly supported by Mr. H. O. Hughes and other speakers who followed. The Parliamentary Secretary to the Ministry of Town and Country Planning, in replying, was able to dispel some anxiety as to the encroachments on Cannock Chase itself, but it still does not appear that the Government realizes the extent of public feeling or the gravamen of the criticism of piecemeal procedure.

This is one reason—a very practical and short-term one—why the prospect of much natural beauty being damaged or rendered inaccessible is so alarming at the present time. Fortunately, the position is not yet irretrievable. There have been instances of forbearance and understanding which demonstrate recognition on the part of military authorities that the love of natural beauty is a valid consideration, as tangible if not necessarily as weighty as agriculture, mining or defence; and the reports already noted bear evidence that the preservers of the countryside recognize that the Service authorities, like public undertakings, are servants of the State, carrying out to the best of their abilities the duties which their service lays upon them.

With such considerable measure of goodwill and elbow room to work in, provided only the individual proposals are not considered in isolation but in relation to other alternatives in the national picture, there should be fair prospects of general agreement between the interests involved.

QUANTUM MECHANICS

The Principles of Quantum Mechanics

By Prof. P. A. M. Dirac. (International Series of Monographs on Physics.) Third edition. Pp. xii+312. (Oxford: Clarendon Press; London: Oxford University Press, 1947.) 25*s.* net.

IT is now twenty years since the theory of quantum mechanics was founded, and not much less since the first edition of Dirac's book was published. Ever since, it has been a classic of scientific literature.

The importance of the development which has taken place in these twenty years can scarcely be fully gauged at present. The whole of the atomic world has been opened up for exact treatment and understanding in a way which can only be compared with the development of mechanics since Newton; and so rapid has the progress been that already large-scale practical applications of quantum mechanics have been made. Moreover, and more important still, there is no doubt that quantum mechanics implies a profound departure from the way of thinking which is characteristic of classical physics. This feature, the philosophical consequences of which are up to now scarcely fully realized, will have consequences which will perhaps make themselves felt only after a considerable time, just as the impact of exact science on European thought and life became noticeable only a long time after Newton.

The text-book literature on quantum mechanics is still in an unsatisfactory state. The much-wanted text-book, of some 1,000 pages, giving a balanced account of all the important aspects of the theory and a selection of the most typical applications, has not yet appeared. Dirac's book certainly does not profess to occupy this place. It is not a book for the student who wants to learn quantum mechanics; but no one who wishes to have a thorough insight into the subject, provided he has gained a first knowledge of it, can afford not to study Dirac's book very carefully. The condensed and crystal-clear style, characteristic of the author, makes delightful and satisfactory reading, especially for someone who, (like the reviewer) thinks that this, rather than the descriptive style, is more appropriate for subjects of this kind.

The author has chosen a straight, one-line approach to the subject, and this is the more formal axiomatic approach. It is very satisfying from the logical point of view, but not, of course, the best pedagogical way to introduce a student to quantum mechanics. As in the previous editions, the first 100 pages or so are devoted to the 'framework' of quantum mechanics, that is, the general principles and properties of all those mathematical entities which occur in quantum mechanics: the eigenvectors (the word eigenfunction or wave-function does not occur until much later), linear operators, observables, etc. So, for example, the book begins with the superposition principle of states, and continues by explaining (and postulating) how the 'observables' are represented by linear operators. The principle of indeterminacy is introduced from the start. Nothing so far about dynamics and the equations of motion, which will fill the framework with physical content. All this is much in the same style as in the previous editions, except for a notable change in the notation. The author uses the 'bracket notation' (rather 'bra-c-ket' notation) which he has invented for the purpose. The well-known type of quantity ($\psi_a^* Q \psi_b$) occurring so frequently in quantum mechanics, where ψ_a, ψ_b are the wave-functions of eigenstates a, b, and Q a linear operator, are denoted by $<a|Q|b>$. The author rightly lays emphasis on the fact that all that matters here is not what function ψ_a is, but what states a and b are and what Q is. It is also emphasized that ψ and ψ^* are never mixed up in quantum mechanics; they occur *always* after and before the operator Q, respectively, whereas the fact that ψ^* is the complex conjugate to ψ is less fundamental. This is brought out by the notation $<$ and $>$. The vectors $<a$ and $b>$ are called 'bra' and 'ket' from the word 'bracket', which describes the notation used in print. Its two syllables, one of them mutilated (for symmetry reasons, obviously) by the loss of the letter 'c', are promoted to the full rank of nouns and important mathematical and physical content is conferred upon them.

In the second third of the book the laws of quantum dynamics are developed. After an exposition of the equations of motion, the angular momentum and the spin are introduced, and a few applications to the hydrogen atom, perturbation theory and the general theory of collisions (with the important representation in momentum space) follow. Also here the main difference compared with previous editions is the notation.

In the last part of the book the many-body problem, the relativistic wave equation and the theory of radiation are treated. Here important alterations and additions are made. In the treatment of an assembly of 'bosons' ('bosons' and 'fermions' are particles obeying Bose and Fermi statistics), the elegant and powerful method of Fock is used which the author has himself applied and developed in his work since 1940. This is applied to the radiation field, that is, an assembly of photons. The author treats a photon on exactly the same footing as any other type of particle obeying Bose-statistics, which is justified in quantum theory. On the other hand, one might perhaps also mention the difference that exists between charged and neutral particles when talking of them as particles in the classical sense. In particular, it seems that photons cannot in the classical limit be considered as particles at all in the sense that a charged particle can.

The last few sections of the book contain somewhat controversial matter. In the treatment of the interaction of radiation with electrons, the author uses the λ-limiting process which was originated by Wentzel, in order to remove the infinite self-energy of a classical point-electron, and was later extended to quantum theory by the author. In reading these sections of the book, one gets the impression that the author firmly believes in this procedure as a remedy for part of the difficulties of quantum electrodynamics; whereas it is mentioned at the end of the book that, nevertheless, fundamental difficulties occur here. It might be mentioned that not all who work on this subject share the author's opinion about the physical correctness of the λ-procedure, although this is, of course, a most interesting and stimulating theory.

In the new version, as in the old ones, Dirac's book will play the part it has played before: it is the standard work in the fundamental principles of quantum mechanics, indispensable both to the advanced student and the mature research worker, who will always find it a fresh source of knowledge and stimulation.

W. HEITLER

MODERN GENETICS

Genetics

By Edgar Altenburg. Pp. xii+452. (New York: Henry Holt and Co.; London: Constable and Co., Ltd., 1946.) 16*s*. net.

THE teaching of all subjects is bound to be influenced by its object. That object ostensibly has always been to expand the mind of the pupil, accustoming it to new modes of thought and to their application in practice. For such a purpose the new development of the science of genetics is remarkably well suited. All types of scientific method have been used in this development and all aspects of human life and thought are affected by its practical application. The only difficulty is that teachers are lacking, and most of those who want to learn have to turn to books. That is why a new book on genetics is so important at the moment.

Dr. Edgar Altenburg, the author of the present work, comes from the famous *Drosophila* laboratory at Columbia. His book is intended for university students. It follows a plan now commonly adopted for such books in the United States. It omits references to original papers, devoting, on the other hand, as much as a third of its matter to summaries of each chapter and to statements of problems, or examination questions; both of these are accurately indexed—more so, indeed, than the text.

It might be objected that this method encourages the novice to acquire fixed and final ideas on each aspect of the subject before the matter is further developed. This objection does not, however, apply to the present case, for in fact matters are not further developed. In the general treatment ideas are not joined together. A work on anatomy or systematics would not perhaps be seriously impaired in its educational use by such incoherence. A work on genetics, however, is bound to suffer. That the author has never felt any difficulty of this kind is apparent from such a sentence as the following, from Chapter 1 (which he puts in italics as being of special moment), "We may then define heredity as the transmission of the germ plasm from parents to offspring"; and the germ plasm he has defined six lines earlier as "the hereditary material". Similarly, in the text of Chapter 2, he tells us that "The question 'Which is more important, heredity or environment?' raises a problem which really has no answer"; but in the summary of the same chapter the wisdom of this remark has been distilled into "Heredity and environment are equally important in the development of the individual". You pay your money and you take your choice. Again, in Chapter 11, the author devotes a great deal of trouble to explaining how crossing-over takes place between paired chromosomes at meiosis. But in Chapter 1 he has already described the two divisions of meiosis as reductional and equational, a terminology which has no meaning where crossing-over takes place. Genetics used to be like this thirty years ago. But need it be so to-day?

So much for modern aspects of the subject—and Altenburg claims to be really modern. Genetics, however, is less modern, as well as more modern, than he imagines. The theory of natural selection, an integral part of modern genetics, can be usefully connected with the work of Darwin. The chromosome theory of heredity can likewise be usefully connected with Weismann and the classical school of German cytologists. Yet the contributions of Weismann and Darwin are referred to only among "problems". There is no argument in the text which requires their introduction: Darwin is mentioned only as the author of the pangenes and the father of a large family.

In place of ancient history, Altenburg offers the most recent of his own ideas: "Some species seldom mutate, as judged by the fact that they have so few varieties. This, for example, is true of the goose. By contrast there are many varieties of chickens, due perhaps in part to a relatively higher (*sic*) mutation rate" (p. 347). Has a conclusion been reached? Probably not. But certainly it would be difficult to create more false impressions in three sentences. One wonders what the author would have made of Fisher and Haldane, Sewall Wright and Vavilov, if he had mentioned them.

Altenburg's book has one thing in common with genetics. It is founded on Morgan. It does not, however, integrate Morgan's ideas with the great achievements of those who came before him and of those who have come after him; on the contrary, it merely fills them out with such intellectual roughage as has been quoted. Such matter can be read, to be sure, without danger of expanding the mind of the student or the teacher, or of finding practical application. But it is not modern genetics.

C. D. DARLINGTON

PRACTICAL VERTEBRATE ANATOMY

Atlas of Outline Drawings for Vertebrate Anatomy

By Prof. Samuel Eddy, Prof. Clarence P. Oliver and Asst. Prof. John P. Turner. Pp. vii + 80. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1947.) 12*s*. net.

THIS is one of those books of outline drawings which are so popular in the United States. There is neither text nor indication of how the dissections should be carried out; but for each animal unlabelled diagrams are given of the important external and internal features, including the system of skeletal muscles. The main types dealt with in detail are *Amphioxus*, the dogfish, *Necturus*, and the cat.

From almost every point of view the book is unsuitable for use in Britain. Of the four main types, only *Amphioxus* and the dogfish can easily be obtained here, but an even more serious criticism is that of the use for which the book is designed. Its aim, as set out in the preface, is to save the student the necessity of "laborious drawing", and to meet the needs of those "with little drawing ability". All that remains to be done is to add labels to the diagrams provided. Such a method of undergraduate training cannot be too strongly condemned. Whether or not the student happens to be naturally clever with his pencil matters little. What does matter is that he should be forced by the act of attempting to draw to make close observation of the specimen before him. In no other way can he easily be trained to pay attention to detail, and in no other way can his attention to detail be checked. It is also not unimportant in the training of any zoologist that he should be given abundant practice in the craft of making clear drawings of his work. Whatever part he may ultimately play as a zoologist, he will have constant need of this ability.

For these various reasons this new atlas cannot be recommended.

W. S. BULLOUGH

Modern Paper-Making

By Robert Henderson Clapperton and William Henderson. Third edition. Pp. xii + 380. (Oxford: Basil Blackwell, 1947.) 30*s.* net.

THIS is the third edition of a book first published in 1929, when it at once established itself as a standard work on the practical aspects of paper-making. It owes this status to a somewhat rare combination of qualities, for not only does it contain valuable information, but also this information is imparted in a straightforward and understandable style. Since the authors are practical paper-makers of wide experience, it is understandable why their book has played such an important part in educating a younger generation of paper-mill workers.

It is with this in mind that a reviewer's comments must be judged. It may be argued that chemistry and physics should figure more prominently, especially in view of the increasing importance of the paper-mill laboratory. The answer is that the treatment is adequate, having in mind the requirements of readers of the above type. The opportunity of a third edition might also have been used to make some reference to the complete change in the raw materials situation since 1939, and in particular to the importance of straw and the wood pulp shortage, since the former has probably come to stay and the latter has reacted so strongly on the everyday life in Great Britain. On the other hand, the writers have confined themselves so strictly to practical paper-making matters in other respects that their decision that there has been insufficient change in general paper-making practice since 1941 to warrant rewriting the book must be accepted as wise in the circumstances.

The scope of the book covers fibrous raw materials for paper, boiling, bleaching and washing methods, beating and other beater operations, the paper machine (six excellent chapters, including one on newsprint manufacture), hand-made paper, finishing methods, paper testing, water supply and soda recovery. There are 157 clear illustrations, and the book concludes with an appendix of useful tabular matter, and an index.

It is a pleasure to be able to recommend this book unreservedly to all interested in the practical aspects of paper-making, and particularly to the student.

JULIUS GRANT

Lecture Experiments in Chemistry

Third edition, with Supplement. By G. Fowles. Pp. xvi+612. (London: G. Bell & Sons, Ltd., 1947.) 25*s.* net.

IN this, the third edition, some sixty experiments have been added as a supplement at the end of the book, and the bibliographies have been brought up to date. On the historical side, information which the author has found in "Chemical Pastime", by F. Accum, 1817, has led to the revision of the dates to a number of the experiments.

In Part 1 of the Supplement there are many valuable experiments, some of which deal with subject-matter not previously treated in the book, as, for example, osmotic pressure, indicators, soluble anhydrite as a drying agent, and the cleaning of mercury, while others are supplementary to those given in the previous edition. In this category all teachers of general chemistry will welcome the experiments on electrolysis with J. A. Mattuck's improved cell.

In Part 2 of the Supplement, experiments are described which will serve as an introduction to the effects of temperature, pressure and concentration on equilibria. In general this section is well done, but it is a pity that the experiments on the solubility of hydrogen chloride and sodium nitrite will not make it clear to the student that it is the heat change at the point of saturation which decides the effect of temperature on the solubility of a substance.

The previous editions of this book have received a very warm welcome and the reviewer is confident that this one will meet with a similar response; it is, indeed, a book which no teacher of general and inorganic chemistry can afford to be without. The publishers are to be congratulated on the good quality of the paper and binding.

Peach Orchards in England

Being an Account of How to Grow Good Peaches in this Country. By Justin Brooke. Pp. 86 + 12 plates. (London: Faber and Faber, Ltd., 1947.) 7*s.* 6*d.* net.

MR. JUSTIN BROOKE is an enthusiast with a sense of proportion. He grows fruit commercially on a considerable scale near Newmarket, has grown and marketed peaches since 1936, and outlines, in the present volume, details for a great expansion of the crop in Great Britain. The variety Peregrine yields heavy crops and is self-fertile; it is best grafted upon the Broad Leaf Mussel stock. The author considers that peach blossom is rather less sensitive to damage by spring frosts than Victoria plum blossom. Manuring should be directed towards the production of vigorous growth, and pruning should also be subordinated to the same end. Thinning of fruit to one every four inches of branch is necessary, and the would-be grower will find adequate detail of all cultural aspects, and of pest and disease control, in the text and in the twelve excellent half-tone plates. Mr. Brooke points out that mechanized corn-growing and fruit production go well together, and it is greatly to be hoped that some of his readers will be stimulated to repeat his experiment in other parts of Britain. It would indeed be a national asset if peaches were within the economic reach of all members of the community.

Les plantes et la vie

Par Prof. Florian Cosandey. (Sciences et médecine, Série des Sciences naturelles.) Pp. 190+10 plates. (Lausanne: F. Rouge et Cie.; Paris: Masson et Cie., 1945.) 210 francs.

THIS book, as stated in the introduction, is written for readers used to university lectures, but who are not specializing in science. It is written by the professor of botany at the University of Lausanne. The material is well chosen and the style attractive. The fundamental physical and chemical features of plants are described and illustrated by diagrams which bring out these relationships with clearness. Such matters as vitamins and hormones are briefly introduced to the reader, and the importance of molecular films is discussed in relation to the surface activity of the vacuole and cytoplasm. The general metabolism of the plant is treated in outline and the characteristics of organic acids, albumins, proteins, glucosides and alkaloids described. A chapter follows dealing with cell structure. There is a preliminary chapter which gives an outline on physico-chemical conceptions which will aid the non-scientific reader to appreciate the following chapters.

It appears that this is only one of a series of similar books dealing with various aspects of science and medicine.

AN ESSAY IN CORRELATION ARISING FROM ALKALOID CHEMISTRY*

By SIR ROBERT ROBINSON, F.R.S.

THE incident which I wish to describe is of peculiar interest, because it transpires that the behaviour of a natural product can only be explained in the light of knowledge comparatively recently acquired and never previously brought to bear in the analysis of a structural problem.

When we break up molecules in order to examine the fragments, or submit them to transformations in order to recognize the reactive groups, the changes that occur usually follow relatively simple rules; the pieces, for example, are clearly related to the whole from which they were obtained. In certain classical instances the picture has been confused by rearrangements of atoms within the molecule in the course of some of the changes examined.

But these molecular shifts also follow laws which have gradually been brought to light, and it has always been possible to integrate the data in terms of a particular molecular structure.

Thus camphor showed itself to be a chemical proteus and at one stage it was not clear which manifestation corresponded to the reality. The vagaries of this molecule which proved most puzzling were explained by Lapworth. Camphor and all its derivatives have been synthesized and thus all dubiety was resolved.

Brazilin is another molecule which twists itself into contortions, and here again we can follow all the varied transformations, and we have the confirmation of synthesis, not, it is true, of brazilin itself, but of many of its more important derivatives.

But the star performers in the team of molecular acrobats are undoubtedly the alkaloids of the morphine group, and I shall speak especially of thebaine.

In 1923–25 I discussed the chemistry of morphine, codeine and thebaine with John Masson Gulland, whose untimely death in a recent railway accident was so great a tragedy. We arrived at a solution of the problem which has since been generally accepted, but there is no synthetic proof that applies to the thebaine structure itself. The certain knowledge from analysis and synthesis relates to the various transformation products, and the molecular structures of many of these are established beyond doubt. The validity of our formulæ, therefore, is estimated entirely on their success in interpretation of a complex of data. With an emendation in one group of products, suggested by Schöpf and gladly accepted, it seemed that the book was all but closed. Yet the most remarkable rearrangement of the molecule and one of the most extraordinary changes yet encountered in the whole domain of organic chemistry remained to be recognized. It subjected the Gulland–Robinson formula to a very severe test, and its triumphant emergence from the ordeal was at one time in doubt and has only been guaranteed during the last two months.

In 1905 Freund treated thebaine with phenylmagnesium bromide and obtained a new base, phenyldihydrothebaine, which was just thebaine to which the elements of benzene (C_6H_5, H) had been added. Similar substances were made later using other organo-metallic reagents, and Lyndon Small and his collaborators have carefully re-examined and extended the series. They have established some intriguing stereochemical relationships and corrected mistakes of other workers.

In 1943, in the course of a visit to Washington, I was privileged to hear of Dr. Small's results and to examine the detail of his brilliant experimental work. Two conclusions appeared to me then to be inescapable; but the full solution of the mystery remained elusive. In September of this year Dr. Small kindly sent me the manuscript of a paper intended for publication in the *Journal of Organic Chemistry*. He had been unable to make any use of my views; and further correspondence showed why that was so, and also led to the understanding that the present disclosure should be made. A new idea, based on the postulates of 1943, then occurred, and the validity of this has recently been indicated by a crucial experiment.

The first of the inescapable conclusions to which I have referred is derived from a comparison of thebaine with phenyldihydrothebaine. The latter is outstandingly more stable. It is hard to hydrogenate in the presence of a catalyst (thebaine is easily attacked), and when reduction does occur all that happens is a break of a C—N bond. Thebaine is very easily hydrolysed as an enol methyl ether; but although phenyldihydrothebaine contains this methoxy group (also one other OCH_3 and a phenolic OH), it is not hydrolysed by hot concentrated hydrochloric acid. But hot hydrobromic acid produces the change $(OCH_3)_2(OH) \rightarrow (OH)_3$, and the action of diazomethane on the trihydroxy-compound gives a trimethoxy-compound which is the methyl ether of phenyldihydrothebaine. From these facts it is perfectly clear that the near-aromatic nucleus of thebaine, which bears the hydrolysable methoxyl, has become truly aromatic in phenyldihydrothebaine.

The second conclusion follows logically from the first, considered in the light of other data. Phenyldihydrothebaine is optically active and by Hofmann's exhaustive methylation procedure it gives a series of optically active derivatives; this is even true of the second stage in which nitrogen is eliminated. The process is $\text{C—C—N—C—C} \longrightarrow \text{C=C} \vdots \text{NMe}_3 \vdots \text{C=C}$. The two double bonds in this optically active product can easily be shown to be present by diagnostic tests.

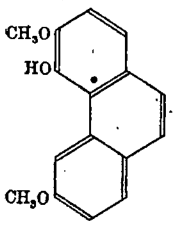
Now phenyldihydrothebaine is a C_{25} base and one carbon atom is in $:NCH_3$ (now lost), two carbon atoms are in OCH_3 groups, and by hypothesis eighteen carbon atoms are in three benzene rings (two of the thebaine skeleton and the phenyl group introduced by the reagent); that leaves only four carbon atoms for the two double bonds. Hence exhaustively methylated phenyldihydrothebaine cannot contain an asymmetric carbon atom and it must owe its optical activity to an *asymmetric molecule* of the type familiar to synthetic chemists and stereochemists but never before encountered in the study of a natural product.

It is easy to guess what kind of an asymmetric molecule is present. Thebaine is easily degraded to phenanthrene derivatives (such as I) and these in their turn are derived from diphenyl (II).

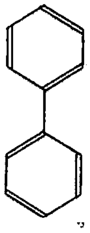
In 1922 Christie and Kenner showed that the dinitrodiphenic acid (III) could be resolved into optically active forms. They also pointed out that this result was explicable if the two rings are assumed to be co-axial (as shown by the dotted line) but not co-planar. In 1926 Turner and Le Fèvre, Bell and

---

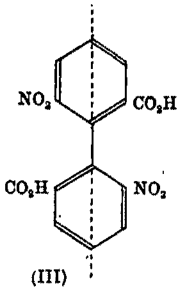
* From the presidential address to the Royal Society, delivered on December 1.



(I)



(II)



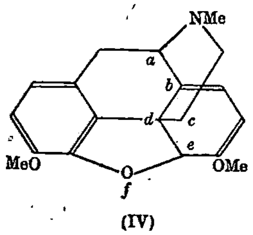
(III)

Kenyon, and Mills developed the hypothesis that restricted free rotation of the phenyl groups is conditioned by the position and size of the substituents. It is well known that this hindrance theory harmonizes all the extensive experimental data.

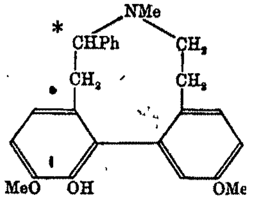
We arrived at the restricted diphenyl idea as a plausible explanation of the optical activity of the end-product of the Hofmann degradation; but there is strong evidence that it must also be applied to phenyldihydrothebaine itself.

Small and his collaborators have shown that Freund's phenyldihydrothebaine is a mixture of two isomerides (equated in various ways, as by reduction, or exhaustive methylation) which he calls (+) α and (+) δ. On heating, (+) α is partly changed to the optical antipode of (+) δ; similarly (+) δ goes partly into the optical antipode of (+) α. The equilibria, reached from either side, favour the α forms. Small clearly recognizes that these changes are partial racemizations but appears to think it possible that a number of asymmetric centres could be inverted in step. He calls the optical antipode of (+) α, (−) α; but it is preferable to term it (−) δ. Thus +, − and α, δ can be taken to be symbols representing left-hand or right-hand at each of two sources of dissymmetry. The partial racemization of (+) α gives then (−) α. These facts alone suggest that the phenyldihydrothebaine molecule contains two sources of dissymmetry and only two; one of these (represented by +, −) is a non-co-planar diphenyl configuration, and the other (represented by α, δ) is an asymmetric carbon atom. We are able to substantiate this view, and the substance is therefore the first in which molecular dissymmetry, and that due to an asymmetric carbon atom (also, strictly speaking, molecular), co-exist. The theory extends to this case without modification; there are the usual numbers of isomerides, 2^n, where n is the number of sources of dissymmetry, not necessarily all asymmetric carbon atoms. This principle is quite obvious but has not previously been enunciated, chiefly because the mixture of asymmetric types is itself new.

All these and many other facts had to be taken into consideration in the endeavour to find a structure for phenyldihydrothebaine, and it would take too long to carry the argument through all its stages. It will be stated more fully elsewhere; meanwhile phenyldihydrothebaine is believed to be (V) and its formation from thebaine (IV) is the result of molecular rearrangement of quite a new type.



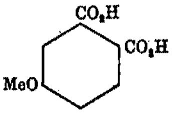
(IV)



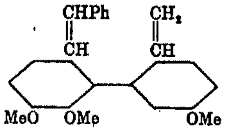
(V)

It was first formulated as a likely process from the electronic point of view. In words: the migrating ethanamine chain is cationoid, (*c*) is joined to (*b*) by means of the electrons of the link (*a b*); the electrons in (*c d*) go to (*d e*) and fulfil the demands of aromaticity of the nucleus; electrons (*e f*) are then taken by the oxygen atom which acquires a negative charge (on decomposition of the complex by water, a proton is attached to oxygen); the phenyl anion brings a new electron pair to (*a*), replacing those lost to the migrating group (*c*). This connected series of changes can be thought of as starting at either end; namely, attack by Ph—, or assumption of a negative charge by oxygen. As in many other migrations in this group, the driving force is doubtless the tendency of the near-aromatic group to become fully aromatic. The formation of isomerides is due to construction of the —CHPh— group in each of the two possible senses, the diphenyl skeletons being configured in one sense only.

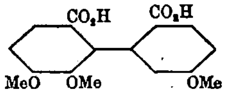
The formula (V) is perfectly satisfactory; examination of models shows that the nine-membered ring allows the phenyl nuclei to be disposed at right angles or at any intermediate angle without strain; there is one asymmetric carbon atom marked * in the formula (V); all the chemical properties and transformations receive natural explanations. But there was thought to be one important exception, and because of it Dr. Small was not disposed (some time before the complete theory was available) to accept the postulation of the two aromatic nuclei. The ultra-violet absorption of phenyldihydrothebaine gave no indication whatever of the appearance of a new aromatic ring in conjugation with the first. This ought to have been thought decisive, but as it conflicted with other equally definite evidence, something had to be jettisoned. Actually a further correlation is possible, and the parts now fit together like a Chinese puzzle made in ivory.



(VI)



(VII)



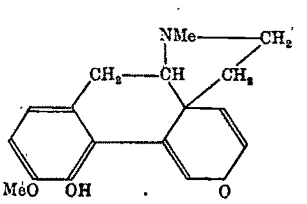
(VIII)

I am indebted to Dr. J. W. Cornforth for pointing out that non-co-planar diphenyls do *not* exhibit normal ultra-violet spectra. This was first noted by Picket, Walter and France (1936), and a clear case is given by O'Shaughnessy and Rodebush (1940). In this example a large ring of eighteen members is formed by a bridge across the *m*-positions of a diphenyl derivative. There is no diphenyl band and only end-absorption.

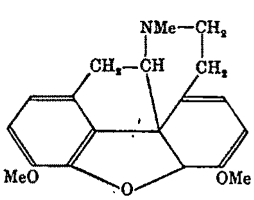
In the last few weeks we have sought and obtained experimental confirmation of the structure (V). Mr. K. W. Bentley has oxidized phenyldihydrothebaine with potassium permanganate and obtained benzoic acid, benzaldehyde, and 4-methoxyphthalic acid (VI). This was identified very thoroughly with an authentic specimen.

By exhaustive methylation, including that of the phenolic group, an optically active product (VII) (made by Freund but stated to be optically inactive) was obtained, and oxidation of this by permanganate in acetone afforded a trimethoxydiphenic acid (VIII). These are very cold, hard facts, and it is to be feared that in the future they will be cited first and all our interesting arguments will be forgotten.

One further punctilio. The thebaine transformations are like the variations of a chess problem in that they have a common key-move. Are we justified in assuming that the problem as set has a unique relation to the variations ? Is the thebaine structure proposed by Gulland and Robinson the only one which serves to explain the whole of the results ? The key-move is the migration of the ethanamine chain from (*d*) to (*b*) in (IV) ; it is only the position *after* the migration that we have proved to be correct. Taking everything into consideration, one alternative can indeed be seen. This can best be explained by reference to the intermediate (IX) now postulated in the complex changes that thebaine undergoes in acid solution.



(IX)



(X)

(IX) arises from (IV) by migration from (*b*) to (*d*) and by hydrolysis. It could equally well arise from (X). The only way of distinguishing between (IV) and (X) seems to be by a study of the α- and β-methylmorphimethines ; and the optical data on these substances strongly support (IV) and would remain inexplicable on the basis of (X). According to Dr. R. Strauss, the ultra-violet absorption of α-methylmorphimethine is not styrenoid and would be consistent with the arrangement, φ.C.C:C.C:C—. On the other hand, that of the β-isomeride shows strong conjugation consistent with φ.C:C.C:C.. The skeleton of (IV) permits these rearrangements and structural elements, but that of (X) does not. The question is related to that of biogenesis and further inquiries must be instituted.

THE INTERNATIONAL METEOROLOGICAL ORGANISATION

MEETINGS IN TORONTO AND WASHINGTON

THE meetings of the International Meteorological Organisation which were held in Toronto and Washington between the beginning of August and mid-October 1947 were of unusual interest, not only on account of the results achieved, but also on account of some of the precedents that were created. It was the first time in its seventy-five years history that any of the constituent bodies of the Organisation had met in the New World, and it was also the first occasion that all ten of the technical commissions had gathered together concurrently.

During the War, the activities of the Organisation were seriously curtailed, but as soon as possible after the return of peace, steps were taken to set its machinery in motion once again. An Extraordinary Conference of Directors took place in London during February 1946 ; new members of the International Meteorological Committee were elected and the technical and regional commissions were reconstituted. This Conference thus cleared the way for a resumption of the international procedures in operation before the War and for the world-wide introduction of improvements in the field of scientific meteorology made by certain countries during the War.

The objects of the meeting at Toronto and Washington were therefore to review and consolidate the progress made since the London conference, to make plans for the future and to consider the structure of the International Meteorological Organisation and its relationship to other international associations.

The meetings of the ten technical commissions in Toronto were spread over six weeks in August and September, and were attended by 179 delegates from forty-four countries. The scope of the proceedings was so wide and the discussions so detailed that even a summary of the activities of each commission would be too lengthy, and attention must therefore be restricted to an arbitrary selection of the main items.

The Aeronautical Commission, which was in session for three weeks, undertook the preparation of a common text for regulations to be adopted by both the International Meteorological Organisation and the International Civil Aviation Organisation for the provision of meteorological facilities to aviation. Codes for the transmission of weather reports to and from aircraft, and for the transmission of terminal and route forecasts between ground stations and to aircraft in flight, required lengthy discussion before agreement was obtained. The Commission for Maritime Meteorology dealt with such problems as marine climatology, the reporting of sea ice by ships, the measurement of ocean waves and swell, and means of increasing the frequency and accuracy of weather reports received from ships. The operation of ocean weather ships and their most suitable stations were also discussed.

The construction of a basic code for weather observations, with specifications for the various elements to be reported, was one of the chief tasks of the Commission for Synoptic Weather Information, and a code acceptable to all countries was eventually devised. Other subjects considered included methods of representing upper-air data on charts, the standard times of synoptic reports and the arrangements for the collection and distribution of meteorological information. The Commission for Instruments and Methods of Observation was formed at the London Conference in 1946, and met for the first time at Toronto, although in the intervening period much work had been done by correspondence. A comprehensive agenda had been prepared, and the Commission surveyed the whole field of meteorological instruments. The discussions usually turned on questions of standardization ; but it was generally felt that only a limited degree of standardization should be the present objective, because much of the equipment in current use was relatively new and capable of further development. It was agreed, however, that comparison of different types of *radio-sonde* is necessary, and recommendations were made for the design of a simple reference instrument. Problems of visibility measurement were also discussed and changes in international practice recommended.

The work of the Aerological Commission has grown in importance owing to the increase in the volume of data relating to the free atmosphere. The regular meetings of the Commission considered, *inter alia*, definitions and specifications of water vapour in the atmosphere, values for certain physical constants in common use and the operation of meteorological reconnaissance flights; but additional sessions were arranged for lectures and discussions at which the trends of modern research were studied.

The increased attention which economic concerns are devoting to meteorology was reflected in the work of the Climatological Commission, which formed a permanent Sub-Commission to examine the applications of climatology to health and industry. The remaining Commissions—those for Hydrology, Agricultural Meteorology, Bibliography and Publications, and for the Projection of Charts—also held successful meetings and made valuable recommendations.

The technical commissions finished their work in Toronto on September 15, and a week later the Conference of Directors opened in Washington. The agenda contained, in addition to some four hundred resolutions submitted by the technical commissions, a proposal to form a World Meteorological Convention, and another to seek affiliation to the United Nations.

With regard to the Convention, the International Meteorological Organisation has hitherto been a semi-official association of Directors of Meteorological Services, but the increased importance of meteorology in a number of directions has led to a widespread belief that the Organisation should be replaced by an inter-governmental body which would be in a more favourable position to enlist official support. The proposal for a Convention gave rise to protracted discussion, and it was clear that some of the delegates were not without misgivings as to the wisdom of a change in the existing organisation. The subject was treated with the utmost frankness, and eventually, after proper safeguards to ensure the equality of meteorological services on technical matters had been provided, a World Meteorological Convention was drafted and signed by thirty-three countries. It will come into force on ratification by thirty countries, and the World Meteorological Organisation will take over the assets and obligations of the existing International Meteorological Organisation, which will cease to exist.

A decision to seek affiliation to the United Nations was quickly reached once the subject of the Convention had been settled. With the assistance of delegates from the United Nations who were present at the Conference, a draft agreement was drawn up which, after approval by a majority of members of the International Meteorological Organisation, will be submitted to the United Nations. If this is accepted, the World Meteorological Organisation will be linked with the United Nations as a specialized agency.

On the technical side, the Conference approved more than two hundred resolutions of the technical commissions, and formed two new commissions, one to study radio-electric meteorology and the other to deal with problems of Arctic and Antarctic meteorology. At two sessions, which were attended by delegates from the International Civil Aviation Organisation, measures designed to co-ordinate the activities of the two Organisations in meteorological affairs were agreed.

The Toronto and Washington meetings, considered either separately or as a whole, were most successful, and well repaid the sustained effort that was required from the delegates. Considerable progress was made both on the technical side and in improving the machinery for applying meteorology to human welfare. One of the most important results was, of course, the signing of the World Meteorological Convention. This decision to effect a fundamental change in the status of the International Meteorological Organisation illustrates the determination of members to adapt the Organisation to modern world conditions. Another promising feature was the emphasis placed upon research, and at the meetings of the technical commissions it was gratifying to notice that the delegates included a high proportion of younger men of science of great ability and originality of outlook.

THE TEAK FORESTS OF BURMA

By Prof. E. P. STEBBING
University of Edinburgh

THERE is probably more romance wrapped up in the history of the great teak forests of Burma, without the addition of the latest war chapter of the Fourteenth Army, than in any other afforested region of similar size in the world. To a large extent the teak tree is itself responsible. Our acquaintance with these forests, so far as the British personally are concerned, commenced with the inquiries into their resources made by the Government after the acquisition for political reasons of the Tenasserim and Martaban Provinces, ceded to the British by Burmese under the Treaty of Yandaboo early in the year 1826. Although the British in India and the Admiralty at home had obtained a certain amount of teak from Rangoon and Moulmein, the largest amount utilized up to this time came from the accessible parts of the teak forests in Malabar on the west coast of Madras. These, in the hands of timber exploiters, were to a great extent cut out by 1830.

Dr. Wallich, superintendent of the Botanic Gardens, Calcutta, was sent to the new Province to report on the botanical features of the forests, and also on their potential possibilities both commercially and for the provision of teak timber required for military purposes. There were great stores of teak in the forests, he said. He advised, in view of the destruction caused in the Malabar forests by unchecked exploitation, that Government should declare its ownership of all teak and that the forests should be managed by Government so as to ensure against their ruin. He added, "No forest exists which can, with propriety, be called inexhaustible—at least none that is liable to constant and extensive demands for timber". The advice was not adopted by the commissioner-in-charge of the new Province. A system of leases was instituted under which the lessee was allowed to take up a block of forest on one or other of the rivers and operate as he liked; the few rules issued were generally disregarded. Moulmein, from little more than a large village, soon became an important town, and within twenty years the whole of the population were immersed in the teak industry to the neglect of any attempt at an improved and extended area under agriculture. A score of years after the annexation, the greater part of the accessible forests had been treated in a fashion similar to the Malabar ones.

The licence method had proved to be a difficult one to supervise and, in the late forties, the Deputy Governor suggested to the Court of Directors that long 99-year leases should be given out in order to interest the licensees in growing teak, a long-term project. Later he earnestly recommended the Court of Directors to give authority to sell the whole of the teak forest lands in tracts of convenient extent and to convey to the purchasers a complete title. The Court of Directors was mercifully too wide-visioned to adopt this suggestion.

The Second Burmese War took place in 1852, the outcome being the annexation of the Province of Pegu on December 20, 1852. Rangoon was the capital, having been founded by the Alompra dynasty in 1775. It had been the principal mart for the export of teak timber for nearly a century, teak being the chief staple industry of the port at that time. The teak tree had been proclaimed a royal tree by this dynasty, and was a royal monopoly, as had been the case with Tippoo Sahib in Southern India, and in the neighbouring Travancore and Cochin States. Following this precedent, soon after the annexation a notification was issued by the Governor-General that all the forests were the property of Government and no general permission to cut timber therein would be granted to anyone. But differences of opinion soon arose between the commissioner appointed to administer the Province and the forest officer. The Governor-General had proclaimed the teak public property, but both the above officials agreed that the Tenasserim royalty of 15 per cent only should be levied on all timber brought down river to Rangoon. The differences between them were on other issues. This led to the famous minute from the Governor-General, Lord Dalhousie, which has been termed "The Charter of the India and Burma Forests". In this he directed attention to his former notification on the ownership of teak, which laid down that the teak timber should be retained as State property. In effect, Lord Dalhousie laid down that the forests were the property of the State, which meant of the public, and that the material in them should be sold at a price the market was prepared to pay—that the system by which the timber merchant made the greatest profit must cease. In the past, big timber firms had been in the habit of getting a permit to take up blocks of teak forest and work them out for teak, paying the Crown a lump sum down and an agreed price per tree or log extracted. The profits, as in the case in Moulmein, of the timber speculators had been excessive, while the activities of the whole people were confined to one business, to the detriment of agriculture.

Lord Dalhousie found a man in Dr. (later Sir Dietrich) Brandis to give effect to his proclaimed policy. Brandis was appointed superintendent of the Pegu Forests in January, 1856, and shortly after to those of Tenasserim. The first step was to put an end to indiscriminate felling in the forests by obtaining some figure of their volume-value in teak, to enable him to prescribe the volume per unit of area which could be safely cut without overfelling in the forest. He instituted his now well-known 'strip surveys'—marching through the forests on a line previously laid down and measuring up on either side all teak trees on a 50 ft. strip. He made four girth classes: 6 ft. and more; 4 ft. 6 in. to 6 ft.; 3 ft. to 4 ft. 6 in.; less than 3 ft. An area of 30 square miles was covered by these linear surveys, on which 2,423 trees of 6 ft. and more had been counted, or an average of eighty trees per square mile. It was estimated that the teak in Pegu was scattered over an area of 7,000 square miles, giving a grand total of 385,000 first-class trees of 6 ft. and more. On this he based the number of trees he could mark for sale each year. The danger of ignorant over-felling was past. The teak had to be girdled when marked and stand in the forests for two to three years to dry; since green teak will not float, and much of the teak was transported from the forest to the market at Rangoon by floating down the rivers. Later calculations of the volumes of teak in the forests made by a more numerous staff proved that Brandis' figures were extraordinarily accurate, considering the rough methods he had to use.

Brandis considered that Government must show the way and prove that the forests could be worked efficiently, the trees felled and logs extracted with the minimum of damage, while, at the same time, the prices received for the timber would repay all charges of felling and extraction and show a handsome surplus. Brandis started work, hiring contractors to fell the timber, drag it to the floating streams and raft it to the sale depots. Local contractors and others more powerful at a distance put every obstacle in the way of the new departure, and it took a man of Brandis' forceful nature to fight and live down this concentrated opposition. The Government was by no means convinced as to the soundness of Brandis' proposition. In its view the first necessity was to ensure that the annual amount of teak timber required by the Government services was forthcoming without any danger of deficiencies: the second that in the first few years working the costs were larger than the receipts. The powerful timber contractors carried the matter to the Privy Council; but the Government's view was upheld in its main contention—that the teak forests were public ownership and should not be worked unchecked by timber exploiters. Brandis soon saw that it would be impossible to work such large areas departmentally, owing to the want of staff and other reasons. He therefore suggested that 12–15 year leases should be granted to approved timber contractors for a definite forest area, the trees to be removed to be marked and girdled by the Forest Department, and the lease be subject to certain definite conditions as regards methods of felling, extraction, etc. This practice is still in force. The other directions in which a true forest administration was commenced in Burma are by now well known. In 1861 Brandis was transferred to India and appointed first inspector-general of forests to the Government of India, and in 1864 the Indian (including Burma) Forest Service was formed, to be officered by men trained in Europe.

The Third Burma War and the annexation of Upper Burma might be said to have witnessed the third advance in forestry progress in Burma. The political reasons are not under consideration. The proclamation of the annexation of Upper Burma in January 1886 was made just sixty years after the annexation of Tenasserim. The new territory placed an enormous area of potential teak and other forests under the Forest Department, the staff of which was far too small to deal with the task. However, progress was made in a remarkably short time by transferring some officers from India.

Once again, and for the last time, the big timber contractors sought to get a free hand in the exploitation of the teak forests in this new Province. Once again the fight was carried to the Privy Council.

But the Inspector-General of the day, Ribbentrop, who had had long experience in Burma as a forest officer, won his case: and all the more easily since it was possible to point to the Pegu Forests thirty years after Brandis had stopped unchecked fellings, and compare them with the position of the cut-out Malabar Forests in 1830 and Tenasserim in 1845.

The reservation of the forests went steadily forward during the last thirty years of the century. Another matter, first enunciated by Brandis, but not actually put into practice by him, was to make use of the nomadic shifting cultivation habits of the Shans and Karens by getting them to sow teak seed or plant in teak plants with their (shifting) cultivation. The idea was not new: both in France and Germany the practice had been in force in the past. In Burma the term 'taungya' had been given to the method, from the Burmese word for shifting cultivation. Considerable patches of young teak poles existed at the end of the century about the country, but as no record or map had been kept they had mostly been lost to sight in the encompassing forest. In the early years of the present century the method fell into abeyance, but was revived at Tharrawaddy during the second decade of the century with very great success. This practice was adopted in the case of *sal* in Bengal and spread throughout India and out to Africa and other parts of the Empire. I saw it in practice by the French forest officers in the Ivory Coast in 1934, copied from the work of British officers in Nigeria.

Forest administration based on sound sylvicultural management and finance made great progress in Burma during the first two decades of the present century. The First World War proved the soundness of the foundations laid. Great demands were made upon Burma to supply the requirements in Mesopotamia, and several other species besides the now commonly used ones, teak and pyinkado, were utilized, some remaining on the market afterwards.

Since the first successful attempt at protecting an Indian teak forest from fire (in the Central Provinces) during the hot-weather season in India had passed successfully, a fire protection system had been devised for all the reserved forests in India and Burma. Fires occurred annually; but the wholesale scale of former times had come to an end. At the beginning of the present century fire protection in the moist teak forests in Burma was called in question. It was found that a low growth of evergreen shrubs covered the forest floor, through which no teak seedling could penetrate. Careful examination showed this to be true in both the moist teak and moist *sal* areas (in India). Fire protection was, therefore, given up save in the very young new woods. As an outcome, a practice termed 'early burning' was adopted, with good results.

To the trained and experienced forest officer, the test of the efficiency, thoroughness and permanency of a forest administration can be studied in one way and one way only—by the presence of working plans in the area of forest administered, the degree of intensity on which the working plans are drawn, and the manner in which they are worked. A forest under a well-drafted working plan, which has passed the scrutiny of the higher forest authority, and been sanctioned by the civil administration of the country, is as safe as man can make it. Such plans laying down the whole management of the forest are usually drawn up for ten-year periods. Burma holds a high place in this important practice of the correct administration of a forest. It is understood that no serious damage to the teak forests was done during the Second World War. Teak is chiefly a timber felled for export. During the War, all teak exports ceased and the Japanese did not undertake any serious fellings in the teak areas, only cutting what they required for their military forces. In 1939 it may be said that Burma could show as fine a series of working plans for great forests from, to quote examples, the plans for South Toungoo and Tavoy in Tenasserim, South Pegu, Zigon and the Northern Shan States, to the Mu and Katha Forests and those of the Chindwin in the north. The work is not finished. For example, some of these working plans have been revised or re-written several times since the early days of the first real working plan (omitting the 'paper' or purely volume statistic plans of Brandis' day) of the early 'eighties. Others are first plans, as, for example, the Mu working plan drawn up for the period 1929–30 to 1938–39.

The total area of the Government reserved forests in Burma in 1938–39 on March 31, 1939, was 20,100,221 acres. The total volume of teak timber felled during 1938–39 was 1,402,548 cubic feet. The total volume of teak timber exported in 1938–39 was as follows in cubic tons: teakwood, 203,596; teak sleepers, 609; teak squares, 59,385; teak conversions, 137,401; teak round logs, 6,209; total, 407,200 cubic tons; teak keys (in tons), 4,753.

That long role of British forest officers which commenced with Brandis more than ninety years ago is now to terminate. They have done a magnificent work for Burma, and have left a great heritage to the Burmans. The latter are now going to take full control of this finely tempered forest administration and these enormously valuable forest estates. In bidding a farewell we can but wish them all success, coupled with the warning that there is no other property in the world which can be so insidiously depreciated, since it inevitably takes a term of years before the effects are perceivable or can be appreciated.

OBITUARIES

Dr. Cyril Strickland

Dr. Cyril Strickland, who died on November 3 in Jersey, aged sixty-six, was born in Cape Colony. He was educated at St. Andrew's College, Grahamstown, and at Oundle School.

After graduating with first-class honours from Caius College, Cambridge, he went to St. Bartholomew's Hospital, London, but before completing his medical course he accepted an invitation to study protozoology at Cambridge under Prof. G. H. F. Nuttall, whose assistant he became. During his tenure of this appointment he found time to take his degree in medicine. He also made the interesting and important discovery that the trypanosome of the rat was normally transmitted from rat to rat through the alimentary route by the mastication of infected fleas and not by the bites of the fleas as had previously been assumed.

In 1912 he went to Malaya to work on the malaria problem on behalf of the Government of the Federated Malay States.

Dr. (now Sir) Malcolm Watson had already been conspicuously successful in controlling by drainage the malaria of the flat coastland of Malaya; but the disease in the upland jungle remained a baffling problem. Strickland has described how, in the course of his work, he found that the jungle in Malaya remained free from malaria until clearing operations produced suitable conditions for the breeding of the vector mosquitoes. This discovery was published in a Government Paper in 1915; its importance was at once recognized, as was shown by the issue of an official prohibition of the clearing of jungle over collections of water without special permission. In India it was hailed as a "brilliant discovery".

In 1922 Strickland became the first professor of medical entomology at the recently established Calcutta School of Tropical Medicine and Hygiene, and during his seventeen years tenure of this post he was able to give a practical demonstration of the value of his discovery by enlisting the enthusiastic co-operation of the medical men, managers and agents of the tea gardens of Assam and north Bengal. The remarkable improvement in the health of the workers in these gardens is believed to have been due for the most part to the policy of maintaining a dense leafy shade over all waterways.

A problem closely studied by Strickland during his long period of fruitful work in teaching and research at Calcutta was the influence of land structure on malaria; he made a special study of the deltas of the Ganges and Brahmaputra and in 1939 published his "Deltaic Formation" (Longmans, Green and Co.). He hoped eventually to correlate the vast amount of data that he had collected regarding the incidence of malaria in eastern India with his survey of land formation, but he was unable to complete this study because of being compelled to retire in 1939 by the superannuation rules of Government. He was then employed by the Army in organising malaria work in Burma, where the campaign was already foreseen. He finally retired from active work in 1942.

WE regret to announce the following deaths:

Dr. Nicholas Murray Butler, for more than forty years president of Columbia University, aged eighty-five.

Mr. S. A. Courtauld, who built and endowed the Courtauld Institute of Biochemistry, and also endowed the professorship of anatomy at the Middlesex Hospital, on December 1.

Sir John Fraser, K.C.V.O., principal of the University of Edinburgh since 1944, on December 1, aged sixty-two.

Prof. Paul Monroe, professor emeritus of education in Teachers College, Columbia University, on December 6, aged seventy-nine.

NEWS and VIEWS

Presentation of Physical Society's Awards:

Charles Chree Medal and Prize

AT the science meeting of the Physical Society at the Science Museum on December 19, the Charles Chree Medal and Prize for 1947 will be presented to Sir Edward Appleton, who will then deliver an address entitled "Geomagnetism and the Ionosphere". Sir Edward has earned an international reputation for his work on the characteristics of the ionosphere, for which he was recently awarded the Nobel Prize for Physics for 1947 (see *Nature*, November 22, p. 703).

Charles Vernon Boys Prize

AT the same meeting the Charles Vernon Boys Prize for 1947 of the Physical Society will be awarded to Dr. C. F. Powell, reader in physics in the University of Bristol, for his development of the photographic-plate technique for the investigation of fundamental particles. Dr. Powell, who was born in 1903, carried out his first piece of research under C. T. R. Wilson at Cambridge on supersaturation in steam. In 1928 he became research assistant to Prof. A. M. Tyndall in the H. H. Wills Laboratory at Bristol, and in 1931 was appointed lecturer in physics there. His outstanding ability as an experimenter became evident in his systematic work on positive-ion emission in pure gases. Until a few years ago the Wilson cloud-chamber method was the only one used in the study of the tracks of high-speed particles, particularly if their energies were to be estimated. It occurred to Powell (and to others working independently of him) that it should be possible to make direct use of the photographic emulsion, in which the fundamental particles would have short ranges and the lengths and directions of the tracks could be measured after development of the plate. He originally used the method in the study of the processes occurring in cosmic rays. In 1938, with the aid of a Cockcroft 700-kV. generator which he had constructed at Bristol, he showed that quantitative information on nuclear processes could be obtained by this method. Since then, with the improved fine-grain emulsions produced by Ilford, Ltd., and with other facilities, he has established this technique as one of the most powerful instruments in nuclear study. It was by this technique that investigators in Joliot-Curie's laboratory discovered triple and quadruple fission in uranium nuclei. Powell himself has obtained range-energy curves for protons and other particles, and the recent discovery of new types of meson by Powell, Occhialini and Lattes has aroused world-wide interest. The presentation of the Charles Vernon Boys Prize will be followed by a brief address by Dr. Powell on the work which forms the basis of the award.

Centenary of the Exhibition of 1851

MR. HERBERT MORRISON, Lord President of the Council, announced in the House of Commons on December 5 that the centenary of the Great Exhibition of 1851 is to be marked by a comprehensive national display in addition to the annual British Industries Fair. It is proposed that the year 1951 should be marked by comprehensive and co-ordinated displays demonstrating British contributions to civilization, in the arts, in science and technology and in industrial design. The Central Office of Information, acting on behalf of the various research councils and other scientific bodies, is to be responsible for the presentation of science and technology. The Council of Industrial Design will take charge of an exhibition of consumer goods, civil transport, some handicraft production and displays showing the historical development of certain industries in Britain. The Arts Council of Great Britain is being asked to arrange, in association with other bodies, a Festival of the Arts, to include events in music and drama, opera and ballet, with exhibitions of painting, sculpture and photography. Arrangements will also be made to cover architecture, town-planning, books and films. No new building will, of course, be possible to accommodate the proposed displays and celebrations. Mr. Morrison emphasized that existing organisations would be invited to collaborate, and also that the provinces as well as London will be able to take a full part in the events, which will be spread over several months of 1951.

"Atomic Physics"

To attempt an intelligible outline of atomic physics on a film which takes about 1½ hours to show is no mean task ; this, however, is what G.-B. Instructional Ltd. have done in the film "Atomic Physics", and it can be said at once that it is done very well. Prof. G. I. Finch, of the Imperial College of Science and Technology, London, gave guidance during the early stages of production, and the advice of Dr. J. D. Cockcroft, Prof. R. E. Peierls and Prof. O. Frisch was obtained. Prof. A. Einstein, Dr. Cockcroft and Prof. Frisch recorded interviews which appear at appropriate places in the film. In addition, the producers were given facilities to use historical apparatus and to photograph modern research equipment to illustrate the development of the theme; among those contributing in this way are mentioned the Royal Society, Royal Institution, Science Museum, Cavendish Laboratory, Imperial College, Research Laboratories of the G.E.C. (England), Messrs. Kodak and Cinema Television. Extracts of films of J. J. Thomson speaking on the electron, and of Lord Rutherford speaking on atomic structure, are included. The Atomic Scientists' Association arranged for one of its members to give technical guidance throughout the film.

The film is arranged in five parts, which can be shown separately. Part 1 is entitled "The Atomic Theory" and illustrates the developments of the nineteenth century, touching on Dalton's work, Faraday on electrolysis, and Mendeléeff's periodic table, and illustrating the current views on molecules and atoms. Part 2 is concerned with "Rays from Atoms" and deals mainly with J. J. Thomson's work. Part 3, on "Nuclear Structure of the Atom", reconstructs the work of Becquerel and the Curies, and is dominated by Rutherford. Part 4, on "Atom Smashing", carries the story up to the work of Cockcroft and Walton, giving also an account of Sir James Chadwick's discovery of the neutron; modern research equipment is illustrated in this part of the film. Part 5, "Uranium Fission", requires little explanation; the atom bomb is dealt with and an idea given of some of the present aims of peace-time research on atomic fission, with a solemn warning of the dangers to mankind if international control of atomic energy is not achieved. Throughout the film, skilful use is made of animated diagrams to demonstrate the mode of action of experimental equipment; this is done by superimposing diagrams upon, and displacing, photographs of the apparatus. The theoretical discussions are also shown diagrammatically. The commentary is brief and to the point; with the recorded interviews, it completes a very able historical survey of the basis, present position and significance of atomic physics.

International Collection of Pure Chemical Substances

At the request of the United Nations Educational, Scientific and Cultural Organisation, and by agreement with the International Union of Chemistry, the International Bureau of Physico-Chemical Standards of Brussels has accepted the task of establishing a collection of pure chemical substances of every kind (metals, alloys, mineral and organic substances, plastics, samples of biological interest, etc.), to place them at the disposal of the laboratories and research workers of all countries, so as to enable them to control the nature and the purity of their own samples, or for any other research work. The expenses of the scheme, including distribution of the samples, will be met by a subsidy from U.N.E.S.C.O. An appeal is therefore being made to all laboratories and research chemists who have prepared, or have at their disposal, such substances in a state of sufficient purity, to send a sample to the new centre with a concise note showing its method of preparation and purification, and its principal constants. If a sample cannot be provided, a description with its constants might be sent, so as to enable the Bureau to establish a register of such substances. It is emphasized that this scheme is not intended to compete in any way with chemical industry, and that products easily obtainable on the market fall outside its scope. Research laboratories of the chemical industries, which often possess samples of rare substances, prepared for their own use in small quantities, and not included in the catalogues of industrial and commercial firms, are invited to co-operate. No samples should be sent without communicating first with the Bureau. Detailed information about the scheme can be obtained from the director of the International Bureau of Physico-Chemical Standards, Prof. J. Timmermans, Université Libre de Bruxelles, 50 Avenue Franklin Roosevelt, Bruxelles, Belgium.

Southwest Research Institute of San Antonio, Texas

The Southwest Research Institute, a non-profit scientific organisation for technological research in support of industry in the south-western United States, was opened in September. Mr. Tom Slick, who is closely connected with oil development and ranching in San Antonio, has given an endowment of more than 1,000,000 dollars. The Institute follows the pattern of the Midwest, Armour and Mellon Institutes in that it will conduct industrial research on a fee basis ; under its charter, sponsoring manufacturers or trade associations retain patent rights on all discoveries accruing from research projects. The dedication ceremonies, at which Mr. Slick was present, took place in the historic old Cable Ranch House, when speakers pointed out that the Southwest Research Institute would provide facilities to the rapidly expanding industrial interests of the south-western States similar to those enjoyed by industry in the north and east. The Institute is the first of a series ; the next is to be built in Houston and devoted entirely to petroleum technology ; an office in the Oil and Gas Building has already been staffed to provide consultation services for manufacturers and processors in the area. The present staff of the Southwest Research Institute includes W. M. Hammond, acting director and business manager, formerly business manager for the Armour Foundation ; Dr. H. C. Dyme, chemist and bacteriologist; Dr. John B. Loefer, biologist and authority on micro-organisms; Robinson Brown, mechanical engineer and oil equipment expert; Dr. Judson Swearingen, chemical engineer and authority on high-pressure processing, blowers and turbines; Dr. Paul A. Keesee, veterinarian known for his work in artificial insemination; Dr. F. W. Bieberdorf, botanist and authority on plant pathology; Mr. I. O. Gilbert, specialist in electronics and machine design.

The first laboratory of the Southwest Research Institute, functionally designed and equipped with modern instruments and machines, houses chemical and biological laboratories, engineering department, a complete machine shop with foundry, forge, tin shop, welding and heat-treating equipment, an animal room as part of the biological section, and various cold rooms, sustained humidity rooms, a self-contained power plant, distillation plant, and other scientific facilities. A separate, underground vault for storage of volatile chemicals is located near by. The Institute is the third and largest unit affiliated with the Foundation of Applied Research, an earlier organisation established by Mr. Slick and other trustees. The first unit of the Foundation is Essar Ranch, widely known for its pure-bred Hereford and Aberdeen-Angus cattle, its experimental cross-breeding of Angus and Brahman strains to produce a hardy beef cattle for tropical regions, and artificial insemination experiments. The second is the Institute of Inventive Research, which provides inventors with a complete processing service without cost.

Coconut Conference

BECAUSE of the present world shortage of vegetable oils and fats, and the fact that the situation is one which will take years to remedy, particular interest is attached to the oil-producing crops, their cultivation, conservation, potentialities and use. During the summer the Coconut Conference (Colombo, July 4, 1947) covered much useful ground, papers, chiefly of a directly practical nature, being devoted to the regeneration of plantations, the use of manures, the value of combining animal husbandry with coconut cultivation, problems of soil conservation, the control of insect pests, and problems of co-operation and marketing of coconut products. This report will undoubtedly prove of interest and value to scientific workers and members of the planting community in other tropical regions where the coconut is an important crop.

Marriage Hygiene

Marriage Hygiene, a quarterly journal published before the War, has been revived. The second series commenced with the issue of August 1947. The managing editor, Dr. A. P. Pillay, is an Indian. He is supported by a staff of editors representing Australia, Britain, China, Europe, the Far East, the Middle East, South Africa, South America, and the United States. It is therefore an international production. The British editor is Dr. Norman Haire, and the distribution in Britain is in the hands of H. K. Lewis and Co., Ltd., 136 Gower Street, London, W.C.1. The annual subscription is 22*s*. The August issue comprises sixty-four pages of articles, notes and comments, reviews and the like. An examination of this material shows that it is a journal of sexology rather than of marriage. Some of the subjects discussed are frigidity, sterility tests, incest, male sexual disorders, transvestism, and necrology. Such a journal, treating sexual phenomena with scientific detachment and in uninhibited detail, should serve a useful purpose in providing a forum for free discussion and the interchange of clinical data. It is to be hoped, however, that the title will be changed to place the emphasis where it properly belongs—upon sex rather than marriage.

Cosmic Rays and Cancer

Sky and Telescope of July has an article with this title, which describes the experiments of Dr. Frank H. J. Figge, of the University of Maryland Medical School, on mice. Male mice were injected with the cancer-inducing substance, methylcholanthrene, and were then distributed in eight cages, five of which were covered with quarter-inch plates of lead. When cosmic rays pass through thin sheets of lead, showers are produced, thus intensifying the effects of cosmic radiation; and the cages were so arranged that various groups of mice were differently exposed to the scattered cosmic radiation during the five months of experimentation. Those so exposed developed tumours in an average period of 8·5 weeks, while 11 weeks were required for those exposed to normal cosmic rays. Other experiments showed the greater susceptibility of mice exposed to cosmic-ray showers. It is true that direct radiation is less effective than secondary showers; but its effect over a life-time seems to be cumulative. Perhaps architects of the future may be called upon to assist in arresting the development of cancer by choosing building materials which will minimize the effect of cosmic-ray showers.

Library of the History of Medicine, Yale

THE report for the year 1946–47 of the Historical Library of Yale University School of Medicine records the safe receipt, with only one damaged volume, of the Klebs Library from Geneva, where it was packed and stored in 1943 by the deputy librarian of the United Nations Library. The report also records the circumstances in which Dr. Henry Sigerist resigned in 1947 the chair of the History of Medicine in Johns Hopkins University, a chair which he had held for fifteen years, in order to devote himself to his eight-volume history of medicine. This great act of devotion to scholarship has been facilitated by the appointment of Dr. Sigerist as a professorial research associate of Yale University, with affiliation to the Historical Library of the School of Medicine. This appointment will enable him to continue his historical work at Pura, near Lugano. The first volume of his history of medicine is now nearing completion and will be published by the Oxford University Press.

Fitzwilliam Museum, Cambridge

THE annual report of the Fitzwilliam Museum, Cambridge, for the year ending December 31, 1946, has been issued. It is the last report with which Mr. Louis Clarke, to whom the Museum is so much indebted, is concerned. His successor, Mr. Carl Winter, formerly deputy-keeper of the Department of Paintings in the Victoria and Albert Museum, London, is now in charge. The report follows the usual lines, and a number of important gifts and acquisitions have been received. Outstanding is Mr. Raphael's great, green jade recumbent buffalo (Han dynasty), which weighs no less than 56 lb. But there are also many other valuable additions to the collections in all the various departments.

Acta Hydrobiologica et Protistologica

A NEW international review on hydrobiology and protistology is to appear shortly, under the above title. The board of editors comprises Dr. G. Alm (Sweden), Prof. H. d'Ancona (Italy), Prof. K. Berg (Denmark), Prof. F. E. Fritsch (Great Britain), Prof. K. Münster Ström (Norway), Prof. William R. Taylor (United States), Mrs. N. Wibaut-Isebree Moens (Holland), Prof. P. van Oye (Belgium), managing secretary. Some seventy leading scientific workers from most countries of the world have promised to support the new periodical, which is intended not only for the publication of original papers on all branches of hydrobiology and protistology, but also for reviews of books and papers, information on scientific institutes, along with a personal section, correspondence, etc. The review is to appear in four quarterly issues of about 100 pages each; the price of each volume of four issues will be 40 guilders. Subscriptions should be sent to A. Oosthoek's Uitgevers Mij, Domstraat 1–3, Utrecht, Holland.

Britain in 1955

"BRITAIN IN 1955" is the theme of a special issue of *Future*, skilfully and collectively produced by a group of experts. The 'high light' is an economic analysis, from the vantage point of 1955, of the preceding decade; but other articles, particularly on the agricultural revolution, industrial relations, the universities, and meteorology, are also most stimulating. In effect, the future is foreshadowed by an informed examination, on specified assumptions, of current trends. A synoptic approach is adopted throughout. There are touches of "The Shape of Things to Come", "Erewhon", and "Brave New World" in judicious combination. An unreal element is the apparent disappearance of serious political controversy. Is this wishful thinking?

U.S. National Research Council Fellowships

THE U.S. National Research Council is again offering a number of fellowships for advanced study and research in the natural sciences. The post-doctoral fellowship programme, administered by the Council for the past twenty-eight years and financed by grants from the Rockefeller Foundation, is designed to permit young men and women who have demonstrated their ability in research in the natural sciences to spend additional time in uninterrupted study. Stipends are at the rate of 2,500 dollars a year, plus travel to the place of study. Since the War, Merck and Co. has supported a fellowship programme in the chemical and biological sciences, designed to stimulate interest in fields of study requiring knowledge of more than one science. These fellowships are therefore designed to give special training to young men and women who have demonstrated marked ability in research in chemical or biological science and who wish to broaden their fields of investigational activity. The annual stipends are in the range 2,500–5,000 dollars, with an allowance of 500 dollars a year to the institution to which each fellow is assigned. A third programme recently inaugurated by the Radio Corporation of America is designed to give special training and experience to young men and women who have demonstrated marked ability in the general field of electronics. Their preliminary experience may have been either in the fields of electrical engineering or physics. Applicants need not have completed more than one year of graduate work, and they must be United States citizens. The fields of study to be undertaken are in the sciences underlying the general science of electronics. Stipends range from 1,600 to 2,100 dollars a year. Further particulars of all these fellowships can be obtained from the National Research Council Fellowship Office, National Research Council, 2101 Constitution Avenue, N.W., Washington 25, D.C.

University of London: Appointments

THE following appointments in the University of London have been announced: Mr. W. D. Hogarth to be clerk of the University Court as from January 1 in succession to Dr. D. W. Logan, who becomes principal of the University on that date; Dr. L. P. Mair to the University readership in Colonial administration tenable at the London School of Economics and Political Science as from October 1, 1947; Dr. N. F. Maclagan to the University chair of chemical pathology tenable at Westminster Hospital Medical School as from October 1, 1947.

The degree of doctor of science has been conferred on Conrad Ellenby, of University College, and on G. M. Dyson, an external student.

The Botanical Society of the British Isles

THE name of the Botanical Society and Exchange Club of the British Isles has been changed to the Botanical Society of the British Isles. New and extended facilities are being offered to members, including the privilege of consulting a panel of specialists. A Conference on "The Study of Critical British Groups" is being arranged in London during April 9–10, 1948. All inquiries should be addressed to the honorary general secretary, Miss M. S. Campbell, c/o Department of Botany, British Museum (Natural History), Cromwell Road, London, S.W.7.

Commonwealth Agricultural Bureaux

THE Executive Council of the Imperial Agricultural Bureaux has decided to change the name of the Bureaux as from January 1 to Commonwealth Agricultural Bureaux. The Bureaux will continue as hitherto in control of the Institute of Entomology, the Mycological Institute, the Bureaux of Soil Science, Animal Health, Animal Nutrition, Plant Breeding and Genetics, Pastures and Field Crops, Horticulture and Plantation Crops, Animal Breeding and Genetics, Agricultural Parasitology (Helminthology), Forestry, Dairy Science, Biological Control and the South American Potato Collection.

Announcements

THE Medical Research Council has recently reconstituted the Dental Research Committee, the function of which is to advise and assist them in the promotion of scientific investigations in this field. The secretary of the Committee is Prof. M. A. Rushton, Department of Dental Medicine, Guy's Hospital, London, S.E.1.

A SERIES of three Christmas Lectures for Boys, on "High-Speed Flying and the Airport", has been arranged by the Institution of Civil Engineers. They will be given by Group Captain E. M. Donaldson, C. E. Foster, and Air Marshal Sir John D'Albiac, on December 30, January 2 and 6, at 3 p.m. Tickets, which are free, can be obtained from the Secretary, Institution of Civil Engineers, Great George Street, Westminster, London, S.W.1.

Chlorocruorin and Hæmoglobin

THERE are four respiratory pigments which circulate in the blood or are found in the body cavity of animals. Two of these, the red hæmoglobin and the dichroic red-green chlorocruorin, are close chemical relatives. Chlorocruorin is confined to certain marine polychæte worms and is characteristic of the group Serpulimorpha, comprising the families Serpulidæ and Sabellidæ. Hitherto it has been thought that all species in this group possess chlorocruorin in their blood. This, however, is not the case. I have found chlorocruorin in twenty-one species of the group, belonging to fifteen genera. One of the species with chlorocruorin is *Spirorbis borealis* Daudin, but another species of the same genus, namely, *S. corrugatus* (Montagu), has hæmoglobin as its blood pigment. Yet another species, *S. militaris* (Claparède), has neither pigment: its blood is colourless. That chlorocruorin and hæmoglobin are really absent here, not just dilute, is proved by the fact discovered by my colleague, Miss Jean Hanson, that the benzidine reaction is negative in the blood vessels of *S. militaris*. These several species of *Spirorbis* live in similar situations, so that the possession of either or neither respiratory pigment appears to be functionally unimportant.

In *Serpula* the blood contains both chlorocruorin and hæmoglobin. It is greenish-brown in colour and has three strong absorption bands in the visible region of the spectrum, namely, the α-band of oxychlorocruorin and the α- and β-bands of oxyhæmoglobin. MacMunn[1] saw this spectrum, but did not recognize the hæmoglobin. Thus for the first time two respiratory pigments have been found in one blood. This duplicity is characteristic of the genus *Serpula*, for it occurs in both the species which I have been able to examine, namely, *S. vermicularis* L. and *S. lobiancoi* Rioja. We have here a chemical generic character that will have to be taken into account by taxonomists; it is comparable with chemical specific characters which the respiratory pigments have already furnished[2].

In one genus only of the Serpulimorpha have I found a respiratory pigment in tissue cells: *Potamilla*, with only chlorocruorin in the blood, has hæmoglobin in its muscles. Just as in the case of mammalian myoglobin, the wave-length of the α-band axis of the hæmoglobin in *Potamilla* muscle is longer than that of the mammalian blood pigment. The muscles of *P. reniformis* (O. F. Müller) are pink with hæmoglobin, whereas those of *P. stichophthalmos* (Grube) have just a little of the pigment. As the two species live side by side in the same stones, again the pigment difference does not seem functional.

The hæm of chlorocruorin is spectroscopically different from protohæm, the hæm of hæmoglobin[3]. Most animal cells contain protohæm[4], whether or not the animals possess hæmoglobin. It is therefore of particular interest to know if animals with chlorocruorin in their blood have protohæm or chlorocruorohæm in the cells of the various tissues of the body. I have studied this question in the Serpulimorpha, particularly in the largest member of the group, *Sabella spallanzanii* (Viviani), previously known as *Spirographis*[5]. By adding pyridine and measuring the hæmochromogen α-band I find that protohæm alone is present in the tissues; it is found in muscles, tube-forming glands, gut wall, nephridia, eggs and sperm. Chlorocruorin, which is in solution in the blood, has never been found in a cell, and its hæm, too, is absent from the cells of Serpulimorpha. Evidently chlorocruorohæm must be formed from protohæm somewhere in the blood system. This conversion has been accomplished *in vitro*[6]. Chemically it is not a big change: one of the two vinyl groups attached to the 4-pyrrol ring of protohæm is oxidized to a formyl group[7]. Cytochrome is widespread in animals[8], and since the hæms of cytochrome *a*[9] and of cytochrome oxidase[6] are very close to chlorocruorohæm, a similar oxidation of the all-pervading protohæm may take place in many animal cells. Incidentally, in the Serpulimorpha I have found no cytochrome.

In the lumen of the gut of serpulids there is a pigment in solution which has a protohæmochromogen spectrum. It recalls helicorubin in snails, and the gut hæmochromogen of *Daphnia*[10]. Presumably it is derived from the protohæm compound in serpulid tissues. What, then, if any, is the breakdown product of chlorocruorin in the blood? Is the chlorocruorohæm again reduced to protohæm, to swell the gut hæmochromogen?

Protohæm is also present in the mucoprotein tube of *Sabella* and in the membranous lining of the calcareous tube of *Protula*. This recalls the presence of chlorocruorin in the mucous jelly tube of Myxicola[3]. What other cases, except pathological ones, are known of the excretion, either into the gut or in skin secretions, of hæm compounds as such—that is to say, not broken down to bile pigments or porphyrins?

A full account of this work, most of which was done at the Zoological Station of Naples, will be published soon.

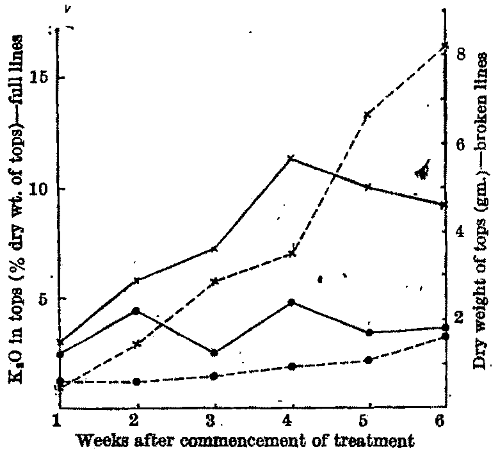
Effect of 4-Chloro-2-Methyl Phenoxyacetic Acid on the Mineral Content and Growth of Plants

Templeman and Sexton[1] have shown that certain concentrations of the aryloxyacetic acids produce a differential effect on the growth of plants of different species. This effect, very marked in the case of 4-chloro-2-methyl phenoxyacetic acid, has now been utilized as a means of eliminating weeds from cereal crops.

We began a study of the mode of action of 4-chloro-2-methyl phenoxyacetic acid on plant growth in 1946. As a result of field experience, rape and spring oats were selected as examples of susceptible and resistant crops, and corn chamomile for intermediate response. Seedlings of the three species were grown in small pots containing silver sand, surface-watered with 40 ml. of nutrient solution (*p*H 6) per pot, once or twice daily according to weather conditions. After three to four weeks, certain pots began to receive nutrient solution to which sodium 4-chloro-2-methyl phenoxyacetate had been added at various concentrations up to 0·5 parts per million, estimated to be the maximum concentration which the most susceptible species could survive. For the following six weeks a given number of pots from each treatment was withdrawn at weekly intervals for examination. The results were as follows.

(i) Rape (*Brassica campestris*). This species was highly susceptible. Chlorosis of the foliage, swelling of the hypocotyl and root tips, presence of adventitious roots and a less fibrous appearance of the roots were marked after only seven days treatment at 0·5 p.p.m. A similar effect was noticeable on the roots after thirty-five days with the concentration so low as 0·05 p.p.m. This was followed by a reduction in top growth (as evidenced by a comparison of the dry weights of treated and untreated plants), very marked at 0·5 p.p.m. and somewhat smaller at 0·1 p.p.m. The proportion of potassium in the tops, which in the untreated plants rose rapidly during the first four weeks under investigation and thereafter remained fairly constant (in spite of increasing dry weight), was restricted in the treated plants to little more than its original low level (see graph). The proportions of phosphorus and magnesium showed no corresponding diminution. The rate of root-growth (as evidenced by a comparison of the dry weights of treated and untreated plants) was not reduced, despite the early change in the character of the roots, until a later stage of development, and even then the effect was small.



CHANGES IN DRY WEIGHT AND K_2O CONTENT OF TOPS WITH TIME IN RAPE PLANTS TREATED WITH SODIUM 4-CHLORO-2-METHYL PHENOXYACETATE AT 0·5 p.p.m.

×——×, K_2O content of control
●——●, „ after treatment
×- - - -×, dry weight of control
●- - - -●, „ after treatment

(ii) Corn Chamomile (*Anthemis arvensis*). This species was moderately susceptible. Characteristic changes in the morphology of the roots and hypocotyl appeared after seventeen days of treatment at 0·5 p.p.m. This was followed by a reduction in top growth (not so marked as in rape) at 0·5 p.p.m., but was scarcely appreciable at lower concentrations. The proportion of potassium in the tops of both treated and untreated plants showed no marked differences (the plants treated at 0·5 p.p.m. gave some indication of a lower proportion of potassium), only falling slightly during the experiment in spite of a 27-fold increase in dry weight. There were no marked differences in the proportions of phosphorus and magnesium and the rate of root-growth was unaffected.

(iii) Spring Oats (Variety "Victory"). This species was most resistant. The roots were unaffected until 28 days after commencement of the 0·5 p.p.m. treatment, and subsequent diminution of top growth was quite negligible. Despite a tenfold increase in dry weight during the period of the experiment, the proportion of potassium in the tops of both treated and untreated plants remained roughly constant. The proportions of phosphorus and magnesium and the rate of root-growth were also unaffected.

Thus, the results show that the sodium salt of 4-chloro-2-methyl phenoxyacetic acid markedly interferes with the potassium metabolism of the most susceptible species. The nature of this interference[1] and its possible bearing on the causes of the selective phytocidal action are now being investigated.

Structure of Dimethylnitramine

ALTHOUGH they are of considerable interest from the point of view of valency theory, aliphatic nitro-compounds have hitherto been very little studied by X-ray analysis, and nitramines, so far as we are aware, not at all. We have now made a crystallographic study of dimethylnitramine and find that the molecule is flat with a considerable amount of double-bond character in the N—N bond.

Dimethylnitramine is monoclinic with $a = 6 \cdot 13$, $b = 6 \cdot 48$ and $c = 6 \cdot 08$ A.; $\beta = 114° 33'$. There are two molecules of $(CH_3)_2.N.NO_2$ in the unit cell (density 1·36 gm./cm.^{3}). The systematic absences of X-ray reflexions show that the space-group is either $P2_1$ or $P2_1/m$, and as the crystals show no pyro-electric effect the latter is more probable, so that the molecule probably possesses a plane of symmetry.

Examination of rotation and oscillation photographs about the b-axis shows that the sequence of intensities along the zero layer line (planes $h0l$) is exactly paralleled by the sequence along the second layer line (planes $h2l$), while the intensities on the first and third layer lines also agree in every detail. This result can only be explained on the supposition that all the atoms lie in two parallel planes $\frac{1}{2}b$ (that is, 3·24 A.) apart, and this can only be so if the molecules are completely flat. More detailed study of the intensities gives no evidence of the smallest deviation of any atom from the one plane; and it seems reasonably certain that all the atoms of the molecules (other than hydrogen, which are presumably distributed statistically) lie on planes of symmetry parallel to (010) in accordance with one of the two alternatives permitted by the space-group $P2_1/m$. It may be noted that the optical properties agree with this conclusion, the minimum index (1·41) being parallel to the b-axis.

If the N—N bond were single, it would be expected that the three bonds N—N, N—C_1 and N—C_2 would be disposed approximately tetrahedrally and certainly not in a plane. The foregoing result therefore suggests that the N—N bond possesses a certain amount of double-bond character, and this is supported by the inter-atomic distances which we have obtained. A large number of X-ray reflexion intensities have been measured, and preliminary Fourier syntheses carried out; the bond-lengths derived from them (all accurate to about ± 0·05 A.) are as follows:

N—O = 1·25, N—N = 1·26 and N—C = 1·46 A.

We prefer to postpone discussion of the theoretical significance of the results until further measurements have enabled us to improve the accuracy of the bond-length determinations; but we emphasize that the value of the N—N bond-length differs from the single bond-length by very much more than the experimental error.

This work was done in the Chemistry Department of the University of Birmingham during 1940–41, under a Ministry of Supply extra-mural contract, and while one of us (W. C.) was the holder of a Fenwick Scholarship and a Brotherton Scholarship; we are indebted to the Chief Scientist, Ministry of Supply, for permission to publish this note.

In the course of the work the numerous trial and error calculations which were necessary before syntheses could be carried out were much expedited by means of a special structure-factor calculating machine devised by one of us[1] and now being improved and rebuilt with the aid of a grant from the Royal Society.

Additional measurements on dimethylnitramine are now being made in order to determine the bond-lengths with the highest possible accuracy, and the work is being extended to compounds containing similar bonds.

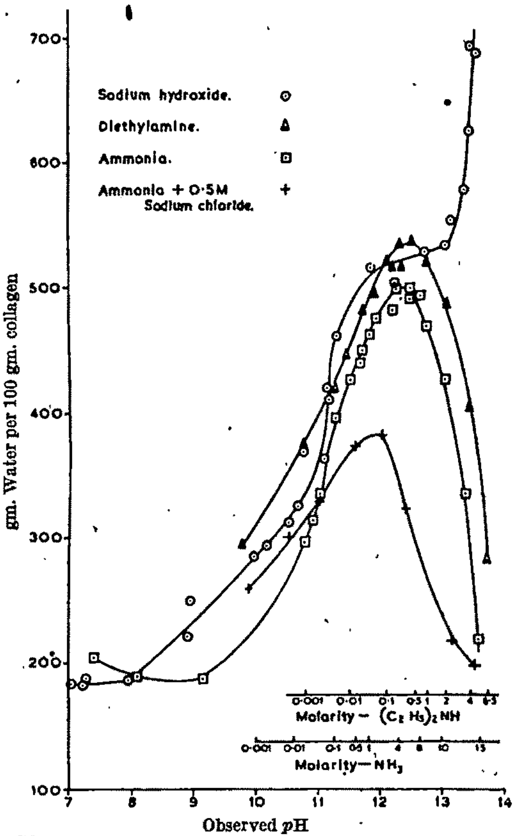
[1] Briefly described by E. G. Cox in the discussion on a paper by Beevers, C. A., *Proc. Phys. Soc.*, 51, 666 (1939).

Uptake of Water by Collagen in Solutions of Alkalis and Strong and Weak Organic Bases

The swelling of collagen and other structured proteins in solutions of strong acids takes place in accordance with the Donnan theory of membrane equilibrium[1,2,3]. Lyotropic effects of anions[4,5] and effects due to fixation of the anions by the protein[6,7,8] can also be observed.

At *p*H values below about 3·0, the water uptake is greater with weak than with strong acids, and the decrease at lower *p*H values is no longer apparent[3,9]; this effect may be attributed to the action of the undissociated acid on the cohesion of the protein[9,10].

We find that swelling in alkaline solutions at 20° is more complicated. With the strong bases sodium hydroxide and tetramethyl ammonium hydroxide, the water uptake of skin collagen does not decrease at high *p*H values as predicted by the Donnan theory, but after increasing less rapidly with rise in *p*H in the range 11·5–13, it increases again sharply as the *p*H is further increased (see graph). (It has been established that the guanidine groups in collagen do not begin to titrate below *p*H 13·5 and hence cannot be responsible for this increase in water uptake.) With the weak bases ammonia and diethylamine, the water uptake changes over the whole *p*H range covered in accordance with the Donnan theory. (The observed *p*H values plotted in the graph were determined using the special Beckman glass electrode; when the concentration of base is high and the activity of water is appreciably less than 1, the observed *p*H values will begin to differ from the true values[11].)



WATER UPTAKE OF SKIN COLLAGEN IN AQUEOUS SOLUTIONS OF ALKALIS AT 20° C.

These results cannot wholly be explained either on the basis of the Donnan theory, or of a specific cation effect. Although there is some indication that the sodium ion may have a specific effect in decreasing cohesion (see below), this effect is small compared with the effects now observed at high *p*H values; and the addition of sodium chloride does not alter the shape of the ammonia swelling-curve, but depresses the water uptake in accordance with the Donnan theory. It must be concluded, therefore, that the increased water uptake occurring at high values is associated with the presence of a high concentration of hydroxyl ions, which by some mechanism, probably breaking of hydrogen bonds, decreases the cohesion of the collagen and so allows it to take up more water. Since this effect is not operative with the weak bases, ammonia and diethylamine, it would appear possible that the presence of undissociated base in some way inhibits the action of the hydroxyl ions on cohesion.

We find that the addition of sodium chloride does not depress the water uptake in alkaline solutions to the same extent as in acid solutions, and conclude that under these conditions the sodium ion or the salt itself decreases the cohesion of the collagen. On the addition of sodium chloride to calcium hydroxide solutions, we find that with concentrations up to 0·05 M the water uptake increases with increasing salt concentration, from 0·05 to 0·5 M it remains approximately constant, and at higher concentrations begins to decrease again. We conclude that at concentrations up to 0·05 M the water uptake increases owing to the effect of the monovalent sodium in increasing the osmotic swelling; at concentrations between 0·05 and 0·5 M this effect, and that of the salt on the cohesion of the collagen, is balanced by the effect of salt in depressing osmotic swelling; and at higher concentrations the water uptake is decreased by the dehydrating action of the salt.

We have also observed that under conditions which reduce the cohesion of collagen, for example, sodium hydroxide solutions above pH 13, the addition of organic solvents miscible with water, for example, acetone, n-propyl alcohol and dioxan, causes the collagen to disperse and to a large extent dissolve.

Effect of Cetyl Pyridinium Bromide on the Water Absorption and Swelling of Soil

SURFACE-ACTIVE quaternary ammonium salts containing a long-chain paraffin group find a number of technical and medical uses due to their adsorption by textiles, bacteria, etc. It has now been found that the adsorption of such compounds by clay particles affects the water absorption and swelling characteristics of soils.

Experiments have been made with a clay loam soil from Harmondsworth, containing 28 per cent of particles having equivalent diameters smaller than 2 μ. This soil was treated with hydrogen peroxide to remove organic matter and then leached with 0·2 N hydrochloric acid to saturate the clay fraction with hydrogen. Groups of four cylinders were then prepared to a constant volume, 1 in. high and 1 in. in diameter, constant weights of mineral matter and of liquid being used in the preparation of each cylinder. Amounts ranging from 0 to 1·0 per cent of a commercial form of cetyl pyridinium bromide were added to the different groups of cylinders, the salt being incorporated in the water added. After preparation, the average moisture content, bulk density and air-voids content of all the specimens was 12 per cent, 1·9 gm./c.c. and 14 per cent respectively. The cylinders were then allowed to stand in a humid atmosphere for three days to permit conditions of equilibrium to be established. After this time the circular surfaces of the cylinders were given a thin coating of paraffin wax, and they were allowed to take up water by standing on saturated sand contained in 100 ml. beakers.

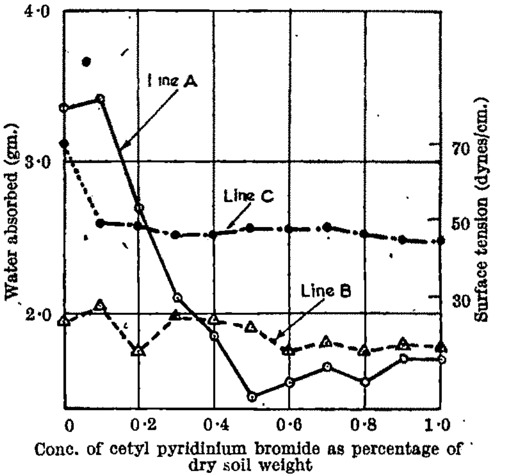

Fig. 1. EFFECT OF CETYL PYRIDINIUM BROMIDE ON THE WATER ABSORPTION OF HARMONDSWORTH CLAY LOAM SOIL

Line A, experimentally determined water absorption; line B, theoretical water absorption to saturate specimens, assuming no swelling; line C, surface tension of cetyl pyridinium bromide solutions of equivalent concentrations

Fig. 1 shows the amounts of water absorbed by the different batches of specimens after 16 hr., each point being the average result obtained from four determinations (line A). The dotted line (line B) indicates the calculated amounts of water required to fill the air-voids in the cylinders, assuming that the latter do not increase in volume. The same diagram shows the surface tension of aqueous solutions of cetyl pyridinium bromide, at concentrations equal to those at which the salt was present in the soil-water (line C).

It will be seen that there is a marked reduction in the water absorption between 0·1 and 0·5 per cent concentration, the reduction being about 57 per cent. The values of the surface tension between the same equivalent concentrations show no such uniform reduction, the variation being about ± 2 per cent. It is concluded that the reduction in the water absorption indicated by line A is not due to a reduction of the surface tension at the air/water interface. Beyond a concentration of 0·5 per cent cetyl pyridinium bromide, there is no further marked reduction in the water absorption, the values reflecting to some extent the volumes of the air-voids in the soil.

It was concluded from this experiment that the addition of cetyl pyridinium bromide to a clay soil will not prevent the movement of water through the pore spaces of the soil, but will inhibit the adsorption of water by the clay particles, and hence the swelling of the latter. More direct evidence for this view is provided by a second experiment, in which measurements were made of the linear swelling of the soil when treated with the same concentrations of the salt.

Flat cylindrical specimens, 2 in. in diameter and 0·5 in. high, were made up at a moisture content of 17 per cent and bulk density of 1·9 gm./c.c. They were compacted between filter papers into brass moulds having perforated bases through which water was allowed to come into contact with the soil. A dial-gauge, reading to 0·001 in., was fitted to the moulds to record the vertical movement of brass cylindrical plates resting on the specimens.

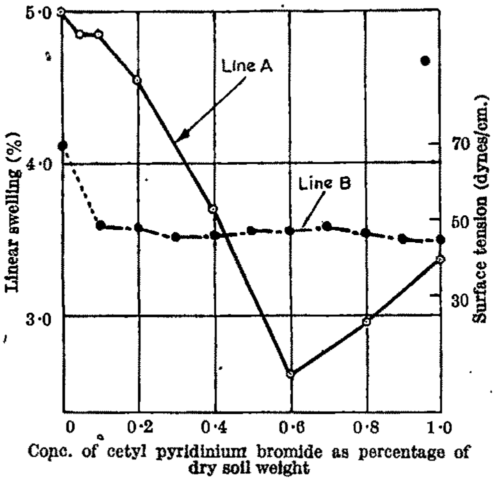

Fig. 2. EFFECT OF CETYL PYRIDINIUM BROMIDE ON THE SWELLING OF HARMONDSWORTH CLAY LOAM SOIL

Line *A*, experimentally determined swelling; line *B*, surface tension of cetyl pyridinium bromide solutions of equivalent concentrations

Fig. 2 shows the linear swelling of the soil specimens, expressed as a percentage of the original height, plotted against the concentration of cetyl pyridinium bromide (line *A*). Each point gives the average value of duplicate determinations. The curve relating surface tension and concentration for aqueous solutions of the salt is reproduced again (line *B*) for comparison. The swelling curve has a similar form to the water absorption curve shown in Fig. 1, except that the swelling reaches a minimum value at 0·6 per cent, after which a steady increase takes place to 1·0 per cent. The maximum reduction of swelling obtained is 48 per cent of the original value for the untreated soil.

It was found in earlier unpublished work that the treatment of soil with an aqueous solution of cetyl pyridinium bromide reduces the heat of wetting. It is considered that the reduction in swelling and water absorption demonstrated in the above experiments may be due to the adsorption of cetyl pyridinium ions on the surfaces of the particles of the clay fraction, which is the component responsible for the swelling properties of a soil, thereby reducing their tendency to hydrate.

I am indebted to Miss O. M. Powell, who carried out the experimental work.

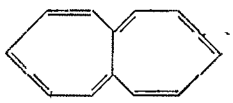
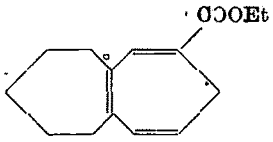
Synthesis of Cyclic Conjugated Polyolefins

CONSIDERABLE interest is attached to the properties of cyclic conjugated polyolefins[1], and in a number of studies we have been exploring possible routes to analogues and derivatives of such mono- and bi-cyclic structures as those of cyclo-octatetraene and azulene. In attempts to prepare the azulene analogue (I), for which the name 'heptalene' is suggested, the ethyl (0 : 5 : 5)-bicyclo-duodecatriene carboxylate (II) was submitted to vapour-phase dehydrogenation by the method of Linstead, Millidge, Thomas and Walpole[2]. The main product of this reaction, however, was a mixture of dimethyl-naphthalenes, formed through rearrangement of the carbon skeleton. In an attempt to prevent such rearrangement, a higher speed vapour-phase dehydrogenation technique was evolved, which allowed very brief contact with the catalyst and rapid removal of the products from the zone of the reaction. Under these conditions the product of reaction was a deep blue oil from which azulene-like material was extracted in small yield with 85 per cent phosphoric acid, and regenerated from solution by addition of water.



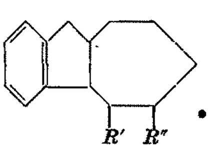
I



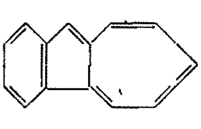
II

This product could be saponified to yield a green sodium salt. A study of its visible absorption spectrum has shown it to have strong absorption maxima at 700, 632, 605 and 580 mμ, and weak absorption maxima at 734, 676, 662 and 651 mμ. These spectral characteristics are very similar to those of 2-ethyl-6-carboethoxy-azulene[3], which shows strong maxima at 668·5, 608·5, 563 (broad band) and weak maxima at 643, 630·5, 619, 586 and 575·5 mμ. Even the best yields of the blue dehydrogenation product have, however, so far been too small to allow of its purification and characterization; and whether a heptalene structure has been produced, or whether an azulene has been formed as a result of a rearrangement reaction, remains to be proved. In either case, however, our experiments to date are significant in that they demonstrate that the heptalene structure is not one which can be generated by dehydrogenation with the same facility as that of azulene. That a careful study of dehydrogenation conditions is essential in the exploration of syntheses of this type is indicated by other experiments.

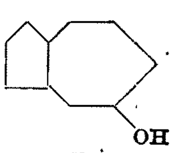
Thus, when a mixture of carbinols (III; $R' = H$, $R'' = OH$ and $R' = OH$, $R'' = H$) was heated with palladium/charcoal at 300° C. for several hours, only a brown resinous substance was produced which gave no addition product with 2 : 4 : 6-trinitrotoluene. Cook, McGinnis and Mitchell[4] have reported a similar failure to prepare 5 : 6-benzazulene by this method. In our hands, dehydrogenation by the method of Linstead *et al.*[2] was equally unsuccessful; but when a higher-speed dehydrogenation was used, there was produced in the first few minutes a trace of a colourless crystalline substance of m.p. 94–97° C. (almost certainly phenanthrene), and this was followed by distillation of an intensely deep blue oil. This yielded 1 : 2-benzazulene (IV) as deep green plate-like crystals on contact with alcohol. It could be recovered unchanged from its solutions in 85 per cent phosphoric acid, and was readily characterized by the formation of a trotylate.



III



IV



V

The higher-speed dehydrogenation method has also been used by us with advantage for the production of azulene from V, the yields obtained being higher than those by other dehydrogenation techniques. Its applications above, as well as to a variety of other structures, will be published in detail elsewhere.

Coprecipitation of Uranous Sulphate with Rare-Earth Double Sulphates

SINCE uranous sulphate forms no double sulphate with sodium sulphate or the rare-earth sulphates which is insoluble in water or dilute sulphuric acid, it might be expected that tetravalent uranium would pass into the filtrates when the cerium group is separated from acid solutions of the sulphates as the double sodium sulphates. Certain cations not necessarily tripositively charged, for example, Th^{4+}, the ionic radii of which are close to those of the cerium group elements[1], tend to be coprecipitated when this group is separated as double sodium sulphates[2], although no corresponding insoluble double sulphates are known. The radius of the uranous ion, however, is almost equal to that of yttrium[1], so there is added reason to expect tetravalent uranium in the soluble double-sulphate fractions. It has been found, on the contrary, that uranous sulphate in acid solution is either partly or wholly precipitated with cerium and the cerium group elements, the extent of coprecipitation depending mainly on the concentration of uranous and rare-earth ions. When the uranium concentration is sufficiently high, a pale green precipitate is obtained, the colour of which is more evident in artificial light.

The following figures were obtained by stirring anhydrous sodium sulphate into a solution of the composition: Ce_2O_3, 32 gm./l.; UO_2, 3·4 gm./l.; H_2SO_4, 106 gm./l., and filtering after standing 30 min. at 20° C. Uranous sulphate was prepared by electrolytic reduction of uranyl sulphate at a lead cathode, air being blown through the solution before mixing in order to oxidize trivalent uranium[3].

Mol. Na_2SO_4 per mol. of Ce_2O_3	1·1	2·2	3·2	4·3	5·4	6·5
Ce_2O_3 precipitated, per cent	72	96	97	97	98	99
UO_2 coprecipitated, per cent	34	71	85	92	95	97

When 6 mol. of sodium sulphate per mol. of Ce_2O_3 were added to a solution of the composition: Ce_2O_3, 24 gm./l.; UO_2, 23 gm./l.; H_2SO_4, 200 gm./l. under the same conditions as before, 80 per cent of the uranous oxide and 99·8 per cent of the cerous oxide were precipitated. The weight fraction uranium oxide to uranium + cerium oxide in the precipitate was approximately 0·43. In a similar experiment with a sulphate solution of the composition: mixed rare-earth oxides, 27 gm./l.; UO_2, 2·7 gm./l.; ThO_2, 3·2 gm./l.; H_2SO_4, 130 gm./l., 98 per cent of the uranous oxide and 98 per cent of the rare-earth oxides were precipitated by 6 mol. of sodium sulphate.

An almost quantitative precipitation of uranous ion can thus be obtained at a rare-earth oxide concentration of not less than 24–32 gm./l., provided that 98 per cent or more of the rare earths are precipitated and that the ratio of uranous oxide to rare earth oxides in solution is 0·1 or less. No significant amount of uranyl sulphate is coprecipitated with sodium cerium sulphate under similar experimental conditions. The precipitate is appreciably soluble in water, both uranous and rare-earth sulphates passing into solution; but the green colour of the precipitate cannot be removed by washing with water.

Earlier work[2] with a solution of the composition: mixed rare-earth oxides, 30 gm./l.; ThO_2, 3·6 gm./l.; H_2SO_4, 109 gm./l. has shown that only 46 per cent of the thoria is coprecipitated with the double sulphates by addition of 6 mol. of sodium sulphate per mol. of mixed oxides. Quite large variations in acid concentration, temperature and time of standing had little effect on this result. There is thus only a qualitative resemblance between the coprecipitation of tetravalent uranium and thorium ions with rare-earth double sulphates. The coprecipitation of thorium, however, is more understandable, since the radius of the thorium ion is some 5 per cent greater than that of the uranous ion and is approximately equal to that of gadolinium.

Although adsorption may play a part in the coprecipitation of uranium and thorium with sodium rare-earth sulphates, it is clear that other factors are involved besides ionic size or ionic charge and the solubility of the double sulphates in the system water – sodium sulphate – sulphuric acid. These must ultimately be traced to the different electronic structures of uranous, thorium and rare-earth ions.

Variation in Density of Cerium Oxide

THE existence of polymeric varieties of cerium oxide was proposed so long ago as 1897[1], this contention being based, *inter alia*, upon the fact that the colour of the oxide is dependent, not only on its purity, but also upon the nature of the salt from which it is prepared by ignition. Although density figures quoted in standard text-books show obvious variation, I have been unable to trace any data correlating the density of cerium oxide prepared in different ways with the possibility of its existence in polymeric forms.

My starting material was cerium oxide of higher than 99·5 per cent purity, the remaining less than 0·5 per cent being other rare earth oxides. This was converted to sulphate with hot concentrated sulphuric acid, and then obtained in solution by diluting with water. Different portions of the sulphate solution thus obtained were then precipitated as oxalate, double sodium sulphate, and as hydroxide with ammonia. Two oxalate precipitates were converted to hydroxide and carbonate by digestion respectively with sodium hydroxide and carbonate; likewise with the double sodium salts. The carbonates and hydroxides were filtered off and washed free of alkalis and soluble salts. One oxalate precipitate was ignited as such, and a further portion of the initial sulphate solution evaporated to dryness and the sulphate thus obtained ignited. All specimens—hydroxides, carbonates, oxalate and sulphate—were ignited gradually and finally at 1,200° C. for 1 hour to ensure complete conversion to oxide.

The cold oxides were then passed through a 100-mesh screen and their densities determined pyknometrically against water at 25° C. Although exceptional accuracy was not aimed at in the density determinations, the results were all obtained under the same conditions, so that, although the values obtained may not be specific, their interrelationship is the same.

		Density	Colour
Oxide 1	Ignition of oxalate	6·64	Light salmon
3	Ignition of hydroxide from double sulphate	6·63	Light salmon
5	Ignition of carbonate from oxalate	6·52	Buff
2	Ignition of hydroxide	6·51	Buff
4	Ignition of hydroxide from oxalate	6·32	Natural
7	Ignition of sulphate	6·27	Light natural
6	Ignition of carbonates from double sulphate	6·03	Yellow

It will be seen that, within experimental error, four oxide forms can be differentiated: oxides 1 and 3; 5 and 2; 4 and 7; and 6; with average densities of 6·635; 6·515; 6·295; and 6·03, respectively. Although it is obvious that the mode of preparation of the oxide, namely, crystal structure and particle shape of the parent compound, influences the density of the product, it is not possible to determine any sequence for this.

If it can be accepted, however, that the polymeric forms of cerium oxide, $(CeO_2)_{40}$, $(CeO_2)_{58}$, and $(CeO_2)_8$, do exist[2], and that these may be differentiated, as may most polymers, by their densities, then it is considered probable on the basis of the above figures that a fourth polymeric form of cerium oxide exists.

X-ray analysis could no doubt verify, or otherwise, this possibility, but in the absence of the necessary equipment for this work, further investigations are being undertaken on this subject from the chemical aspect.

Age of the Baker's Hole Coombe Rock, Northfleet, Kent

Prof. W. B. R. King and Dr. K. P. Oakley discussed this subject in *Nature* of January 13, 1945 [1].

In my opinion the Montières Coombe Rock is Riss I plus Riss II, with Levallois I and II *without any trace of Acheulean.* The coombe rock of Baker's Hole contains a Levallois with large flakes plus bifaces which, according to King and Oakley, resembles my Levallois V industry of broad but not too thick flakes, and abundant heart-shaped and triangular bifaces. Their opinion is probably right, and for some years I have suspected my mistake; but there are two solutions. If, as I am led to believe (without personally being able to control the Northfleet Coombe Rock), Baker's Hole is really Rissian, one must explain the difference in the industries between Montières and this English site.

When I first set forth my views on this subject, my knowledge of the industry of Northfleet and the various French and English Levallois levels was incomplete. In England the true Old Levallois exists in a solifluxion layer at Bapchild, Kent[2]; but it is not the same as that of Northfleet, which is analogous to our Levallois V. In France the Levallois V is not derived from Levallois IV. It may be that, while we had our Levallois III–IV, England had already reached a Levallois stage more or less Levallois V, and that during the low sea-level of the Würm it crossed over to France, driven out of the northern islands by the Würm I glaciation. If the coombe rock of Baker's Hole is Würm, as in France, the Levallois V should be on (not in) the solifluxion gravel; but the contrary is the case in Baker's Hole, where the Levallois is below the coombe rock, which is evidence for making the origin of our French Levallois V a little later.

The same thing applies to the French Levallois III–IV, which is similar to the Markkleeberg industry shown by Grahman to be not Riss–Würm but Mindel–Riss. During the Riss this latter was probably driven back from Germany towards the west, England included. The same industrial stations may, therefore, alternate between the zones of the big glacial extensions and the western zones of less severe climatic conditions, and have taken advantage of the low sea-level draining the Channel at each maximum glaciation.

Let us now return to the Acheulean types of Swanscombe referred to as *superior*, that is to say, Acheulean IV–VII of the Somme. The answer is that in France during the Mindel–Riss the limande (ovate) is the dominant type until the end of Acheulean III (with always sporadic pointed pieces which become more numerous towards the end of Acheulean III and with the appearance, as at Swanscombe, of a few small pieces of Levalloisian technique). In all of the Mindel–Riss deposits at Swanscombe, there are types which are generally found in France in the inter-Riss: Acheulean IV, which is Commont's workshop-level, and which continues after the Riss II (Old Loess with Acheulean V) and finally in the red fissured clay of the Riss–Würm of the 30-metre terrace. This is probably a phenomenon of precession and migration.

Under these conditions, regional differences should not cause surprise. Only careful and *objective* observations can in time lead us to establish these regional differences, which are due to glacial extensions and concomitant continental connexions, alternating between England and the rest of Europe with high sea-levels re-occupying the English channel and the North Sea.

Dependence of Anomaloscope Matching on Viewing Distance or Field Size

I READ with great interest the letters of Mr. R. G. Horner and Mr. E. T. Purslow and of Dr. J. H. Shaxby[1], in which they describe the changes which have to be made in the red and green mixture required to match a given yellow, as the visual angle is altered. They remark, "It is more surprising that such effects should extend to angular fields between 1° and 3° . . ." I have recently confirmed their conclusion and have found that the effects extend to angular fields of between 5° and 25°. I have also performed some additional experiments in an attempt to elucidate the cause of the effect.

Some colour filters were prepared, the properties of which are shown in Table 1.

TABLE 1. SPECTRAL TRANSMISSIONS OF COLOUR FILTERS

Class of filter	Series 1	Series 2	Series 3	Series 4
Dichromatic	0·69μ and 0·55μ	0·69μ and 0·53μ	0·69μ and 0·51 μ	0·69μ and 0·50μ
Monochromatic	0·580μ	0·575μ	0·570μ*	—*
Wide band	0·51–0·70μ	0·52–0·68μ	0·52–0·66μ	0·47–0·62μ
Yellow-blue				0·565μ and 0·450μ

The dichromatic filters transmitted two narrow spectral bands the mean wave-lengths of which are shown in the table. Each of the monochromatic filters transmitted a single band having the mean wave-length shown. The wide-band filters had a broad transmission which occupied a position in the spectrum between the wave-lengths indicated. Four series were prepared, and the filters in each series were adjusted to match one another as closely as possible in hue and saturation, at a light intensity of 50 ft. c. and a visual angle of 5°. Satisfactory matching was obtained except in the cases of the filters marked with an asterisk. The failure to obtain an exact match was due to the fact that the dichromatic filter of Series 3 transmitted a cream-coloured light, and in consequence the monochromatic filter was definitely more saturated. The same statement would have applied even more forcibly to the monochromatic filter in Series 4, since the light transmitted by the dichromatic filter of this series was almost white. Instead of a monochromatic filter, a dichromatic yellow-blue filter was prepared having the transmission shown in Table 1.

The filters in each of the series were now viewed in pairs at visual angles of about 1°, 5° and 25°, with the results shown in Table 2.

TABLE 2. COLOUR CHANGES WITH ALTERATIONS OF VISUAL ANGLE

Filters being compared	Series 1	Series 2	Series 3	Series 4
Dichromatic and monochromatic	4	4	4	–
Wide-band and monochromatic	3	2	1	–
Dichromatic and wide-band	1	2	3	6
Dichromatic and yellow-blue	–	–	–	10
Wide-band and yellow-blue	–	–	–	4

The highest score was given where there was a very obvious colour change with alteration of visual angle. Smaller scores were given in accordance with the visual estimate of the amount of the colour change. Comparing the scores in the four series when the dichromatic are compared with the monochromatic filters, it will be observed that altering the wave-length of the green component from 0·55 to 0·50 produces little or no effect on the score. This suggests that some alteration in the blue sensation is not responsible for the effect, for if it were it would be expected that Series 2 would have a higher score than Series 1, and Series 3 a higher score than either. On the other hand, that some alteration in the red sensation may be responsible is suggested by the fact that the scores for both wide-band versus monochromatic and for dichromatic versus wide-band, are smaller than the scores for dichromatic versus monochromatic. It would be expected that such would be the case if red played an important part, since the dichromatic filters transmit the most red, the monochromatic filters the least red, while the wide-band filters occupy an intermediate position so far as red content in the light transmitted is concerned.

To summarize the facts so far known: (1) with reduction of visual angle, filters which transmit red freely become redder than those which do not, and vice versa; (2) this effect is still found at visual angles as large as 25°.

A Unified Theory of Spontaneous Electrical Fluctuations in Thermionic Valves

THE phenomena of intrinsic fluctuations of voltage and current in electric circuits are generally regarded as belonging to either of two classes, usually referred to as 'thermal fluctuation' and 'shot effect'. The former, the precise counterpart of the Brownian motion of mechanical systems, has its origin in the irregular thermal movement of the constituent particles of matter; the latter, which occurs in thermionic valves and similar devices, is considered to be essentially due to the electronic structure of electricity.

Although it therefore seems that the two phenomena are of an entirely different nature, it has frequently been pointed out that they become identical in certain circumstances[1]. Theoretical considerations have led me to the conclusion that not only in such limiting cases but quite generally the two phenomena are, in fact, only two aspects of one and the same statistical fluctuation process, which can be theoretically treated by the application of the principles of statistical thermodynamics. By following this line of approach, it becomes possible to derive, in a much simpler way than by the established theories, an approximate formula for the shot effect in diodes which covers the whole range of the characteristic. A detailed paper on this investigation is being published elsewhere. Here the main resulting formula only is given, and its application to some special cases discussed.

Let I be the mean current through the valve, V_a the applied anode potential, I_s the saturation current for the filament temperature T, e the magnitude of the electronic charge, and k Boltzmann's constant. Then the mean square of the fluctuation of current, within the interval Δf of the 'frequency spectrum' of that fluctuation, is given by

$$\overline{(\delta I)_f^2} = 2kT\Delta f \cdot \frac{g_c^2 + g_a^2}{g_c + g_a}, \tag{1}$$

where

$$g_a = \left(\frac{\delta I}{\delta V_a}\right)_{I_s} \tag{2}$$

is the differential valve conductivity; and

$$g_c = \left(\frac{\delta I}{\delta I_s}\right)_{V_a} \cdot \frac{eI_s}{kT}. \tag{3}$$

In the so-called 'retarding field region' (with negative 'anode' potential), where

$$I = I_s \exp\left(\frac{eV_a}{kT}\right),$$

one has from (2) and (3)

$$g_a = g_c = \frac{eI}{kT};$$

hence formula (1) becomes

$$\overline{(\delta I)_f^2} = 2eI\Delta f. \qquad (4)$$

It was shown by D. K. C. MacDonald and me that this formula is indeed strictly valid in the retarding field region[2].

In the so-called 'space-charge limitation' region (at the lower bend of the characteristic) one would expect $g_c = 0$ as, according to the Langmuir – Child relation, I should be independent of I_s. This immediately leads to

$$\overline{(\delta I)_f^2} = 2kTg_a\Delta f. \qquad (5)$$

The same relation follows generally for $g_a = g_c$. In any case within this region $0 \leqslant g_c/g_a \leqslant 1$; thus, according to (1), the fluctuation formula can be written in the form

$$\overline{(\delta I)_f^2} = 2eI\Delta f \,.\, \Gamma^2, \qquad (6)$$

where the 'space-charge reduction factor' Γ^2 is given by

$$\Gamma^2 = \lambda \frac{kT}{eI} g_a, \qquad (7)$$

and λ is a constant of the order of magnitude unity. This result is also in agreement with experiment[3].

Finally, in the saturation region where $I = I_s$ is independent of V_a, one has $g_a = 0$, and consequently one obtains Schottky's classical shot effect formula in the form (4).

It has been argued[1] that a diode with two hot electrodes at the same temperature T (double diode) should be equivalent to a 'resistance' $1/g_a$ of the same temperature, and hence the fluctuation should obey Nyquist's thermal fluctuation formula, that is, formula (5) with a factor 4 instead of 2. In order to check this prediction, fluctuation measurements in double diodes were carried out, on my suggestion, by D. K. C. MacDonald some time ago[4], with the result that the relation was satisfied for low temperatures only, and that the ratio between measured and calculated fluctuation increased steeply with increasing temperature. This unexpected result can be immediately understood in the light of the present theory without any further assumptions. For it follows from the theory that formula (1) should also hold for a double diode when the factor 2 is replaced by 4. Thus one obtains the fluctuation formula

$$\overline{(\delta I)_f^2} = 4kTg_a \frac{1 + \alpha^2}{1 + \alpha} \Delta f \qquad (\alpha = g_c/g_a). \qquad (8)$$

This coincides with Nyquist's law only for $\alpha = 0$ and $\alpha = 1$ (and approximately within these limits), but predicts increasingly larger fluctuation values for increasing values of α. From the valve data kindly supplied to me by Dr. MacDonald, it follows, indeed, that α is of the order of magnitude unity up to filament temperatures of about 2,100° K., and from there on increases rapidly with increasing temperature; this is in satisfactory agreement with the fluctuation measurements mentioned.

Production of High-Frequency Energy by Ionized Gases

SINCE the publication in this journal[1] of a note by P. C. Thonemann and R. B. King, entitled "Production of High-Frequency Energy by Ionized Gases", a large number of experiments have been made in this laboratory on the noise and oscillations in cold-cathode and hot-cathode discharge-tubes, when placed in a transverse magnetic field[2]. Our experiments were carried out with nitrogen at a pressure varying from 1 to 50 μ mercury in cold-cathode discharge tubes. The greatest care was taken to localize the magnetic field of an electromagnet, to hold constant the pressure at a fixed level and to purify the gas (spectroscopically pure nitrogen).

The work was done with a superheterodyne receiver covering the range from 1·30 to 2·60 metres, coupled by small condensers to the cathode or the anode on one side, and to a Langmuir probe on the other side. The probe was constructed as described by F. D. Greeves and J. E. McF. Johnston[3] and J. L. Spencer-Smith[4]. Six probes were placed in the discharge, each one along a diameter of the circular section of the tube, and movable by means of a magnetic coil.

The noise occurred only when the magnetic field was applied near the anode of the tube. It fell to less than 10 μV. when the magnetic field was applied near the cathode or near the probe. When the electromagnet was moved from the neighbourhood of the anode, the noise decreased rapidly. This result is very different from that reported by Cobine and Gallagher[5] when working on wave-lengths greater than 50 metres.

When the tube current and the pressure of the gas were constant, the noise-level increased when the magnetic field increased, reaching a sharp maximum for some fixed value of the field. The noise decreased while the magnetic field was increased further until it reached the value where the discharge was cut off. When the tube current was increased, the magnetic field producing the maximum noise was also increased.

With constant pressure and magnetic field, the noise increased when the tube current continuously increased and reached a certain maximum, then decreased to a very low value. The resulting position of the noise maximum moved towards the heavier currents when the applied magnetic field increased. When the applied magnetic field was held constant, the tube current corresponding to the noise maximum increased when the pressure decreased.

The use of probes at fixed potentials showed that the maximum of noise is produced when the potential of the probe is equal to the local potential in the discharge. This result cannot be explained by changes of space-charge conditions far from the probe studied, for it was shown that the variation of potential of a probe did not disturb the space-charge conditions near the other probes even when the magnetic field was applied.

Contrary to the results of Cobine and Gallagher[5], a sharp maximum of noise was found when the probe potential crossed the local potential in all the experiments which have been carried out.

The Cobine and Gallagher hypothesis and the J. J. Thomson – Langmuir theory of electron oscillations in ionized gases do not seem sufficient to explain the results of these experiments.

A complete account of the present work will appear in due course in the *Revue Scientifique*[6].

Gyro-interaction of Radio-Waves Obtained by the Pulse Method

IN March and April 1946, during fourteen nights, experiments were made by the Institute of Technical Physics of the University of Naples in association with the Institut Elettrotecnico Nazionale of Turin, the Vatican Radio and Italian Navy and Air Force, in order to verify if there is a resonance effect in the interaction of radio-waves (gyro-interaction) according with V. A. Bailey's suggestion of 1937[1].

For this purpose a method devised by me was used, consisting in varying the frequency of the disturbing station around the local gyromagnetic frequency, to obtain the maximum of the phenomenon. As soon as the maximum was revealed at the receiving apparatus, the frequency of the disturbing station which has produced the maximum was measured by means of a frequency-meter. This measured frequency is very close to the local gyromagnetic frequency. By doing this, it was possible with a power of 700–800 watts to measure the local gyromagnetic frequency $\Omega = eH/2\pi m$, and consequently the value of the total terrestrial magnetic field H in the ionosphere, and also to ascertain a regular variation of the gyro-frequency during the night.

In order to verify the results of those experiments, further investigations were made between January and July 1947, in association with the Italian Navy. The military stations of Augusta (630 m., 1 kW.) and Taranto (1,250 m., 1 kW.) operated as emitters, and Venice, La Spezia, Leghorn and Roma (Sant' Alessandro) as receiving stations. Naples, the wavelength of which varied from 265 to 285 m., operated as disturbing station.

In order to obviate the lack of power of the Naples station (400–500 watts), which, in the first experiments, made observation of the phenomenon very difficult, the pulse-method was applied to this station. The experiments made using the pulse-method have confirmed my suggestion, because, although the power was not much varied, it is believed that the transient is more efficient than a continuous wave in the interaction.

The gyro-interaction was observed frequently, sometimes during a whole hour of transmission, and very easily, notwithstanding the remarkable strength of the atmospheric static. The number of the observations (about forty) obtained in Venice, and often also in Rome, is sufficient to confirm clearly the gyro-interaction. The phenomenon was never observed in Leghorn and La Spezia, perhaps on account of the fact that the reflexion points of the waves of the emitting stations were too far from the 'sky' of Naples. The wave-lengths of the disturbing station which have caused the gyro-interaction are included between 265 and 282 metres. The variation law of the disturbing station frequency was 4 by 4, 2 by 2, and very often 1 by 1 metre. The behaviour of the phenomenon was generally similar to that in 1946 during the three hours of transmission. While in the first hour the gyro-frequency was low, about 282 metres, in the second hour it became higher, about 272 metres or less, and in the third hour about 265 metres. In 1946 and 1947, the interaction was stronger between 0200 and 0300 local time, and less easily observable between 0400 and 0500.

The experiments are being continued with more powerful stations.

Relativity of Accelerated Motion

ACCORDING to the general theory of relativity, accelerated motion is relative; that, however, is difficult to reconcile with experimental evidence; for example, in the case of rotation.

The relativity of accelerated motion follows from the general covariancy of physical laws; thus, if $T_\alpha^0 = 0$ (for all four components) represents a physical law in one system of co-ordinates, then in any other system the law is

$$T_\mu = \frac{\partial x_\alpha^0}{\partial x_\mu} T_\alpha^0 = 0; \qquad (1)$$

that is, it preserves its form.

Laws of physics can therefore give us no information about the system of co-ordinates used; and, since four-dimensional curvilinear co-ordinates correspond to accelerated motion, the latter is purely relative. This difficulty can be explained as follows.

Equation (1) presupposes that (*a*) there is one to one correspondence between the two spaces, (*b*) the transformations $\partial x_\alpha^0/\partial x_\mu$ remain finite throughout the space; that, however, need not be the case in a transformation between a Galilean and accelerated spaces.

Accelerated motion is equivalent to a gravitational space, and we should expect the latter to have an impenetrable boundary, since otherwise a particle might acquire in it an infinite velocity. For example, in the case of Einstein's gravitational space, the boundary is $r = 2m$. There is, therefore, no one to one correspondence between a Galilean and accelerated spaces.

If a Galilean space can be transformed into an accelerated one, we should expect that on the boundary the transformations $\partial x_\alpha^0/\partial x_\mu$ would become infinite, and (1) would break down. Unfortunately, there are no solutions for accelerated spaces, except in the case of a uniform accelerated motion[1].

The fundamental form in this case is

$$ds^2 = (1 + 2\omega x)\,dt^2 - \frac{dx^2}{1 + 2\omega x} - dy^2 - dz^2 \qquad (2)$$

$$\omega = g/c^2,$$

where g is the acceleration.

The corresponding transformations are

$$x_0 = \frac{(1 + 2\omega x)^{1/2}}{\omega} \cosh \omega t - \frac{1}{\omega}\,;$$

$$t_0 = \frac{(1 + 2\omega x)^{1/2}}{\omega} \sinh \omega t\,; \qquad (3)$$

whence

$$\begin{aligned} \frac{\partial x_0}{\partial x} &= (1 + 2\omega x)^{-1/2} \cosh \omega t, \\ \frac{\partial x_0}{\partial t} &= (1 + 2\omega x)^{1/2} \sinh \omega t, \\ \frac{\partial t_0}{\partial x} &= (1 + 2\omega x)^{-1/2} \sinh \omega t, \\ \frac{\partial t_0}{\partial t} &= (1 + 2\omega x)^{1/2} \cosh \omega t, \end{aligned} \qquad (4)$$

where x_0 . . . refers to Galilean space.

As can be seen from (3), the part

$$\left(x_0 + \frac{1}{\omega}\right)^2 - t_0^2 \leqslant 0$$

of Galilean space has no corresponding points in the curved space; the boundary is at $x = -1/2\omega$, and the transformations (4) become infinite on the boundary.

A phenomenon which can serve as a test is the rate of radiation of an accelerated electron; it is equal to the Poynting's flux:

$$\int \rho_n dS. \qquad (5)$$

In the case of a uniform rectilinear motion, (5) vanishes, and there is no radiation.

To find the radiation in accelerated motion, (5) is transformed to the new co-ordinates (3); the flux corresponding to the transformed tensor does not vanish; it leads to the correct value of the rate of radiation of an electron moving with acceleration g.

It is important to notice that the flow of energy takes place only through the singular plane $x = -1/2\omega$.

A Statistical Criterion to Determine the Group to which an Individual Belongs

In a previous note[1], I have discussed the logical problems involved in the classification of an individual into one of two groups to which he can possibly belong. Some observations were the same as those given by Welch[2] in an earlier note. The solution derived above was identical with the discriminant function proposed by Fisher for this purpose. The corresponding problem when the individual has to be specified as a member of one out of many groups to which he can possibly belong does not appear to have been tackled. The following solution, which comes out as an obvious extension of the discriminant function analysis, has been derived so as to satisfy a logical set of requirements.

Let $\pi_1, \ldots, \pi_k$ be k populations with the corresponding probability densities $f_1, \ldots, f_k$, each containing p measurements on an individual as variables. If an individual can be represented by an ordered set of p measurements or a point in a space of p dimensions, then the problem requires a division of the space into mutually exclusive regions $R_1, \ldots, R_k$, with the rule of procedure of assigning an individual to π_i if he belongs to R_i.

Let $P(I \subset R_i \mid \pi_i) = \beta_i$ denote the probability of an individual I of π_i falling in R_i. If the above rule is applied to a collection of individuals in which the proportion of those belonging to π_i is p_i then the proportion of misclassifications will be $1 - (p_1\beta_1 + \ldots + p_k\beta_k)$. If this has to be made a minimum, then using the calculus of variations one finds that the region R_1 is to be chosen as $p_1f_1 \geqslant p_2f_2$, $p_1f_1 \geqslant p_3f_3, \ldots, p_1f_1 \geqslant p_kf_k$, and similarly the regions $R_2, \ldots, R_k$; it is easy to see that the regions so constructed are mutually exclusive and they cover the whole p-dimensional space.

In case the p's are not known and the individual is equally likely to have arisen from any group, the solution is obtained by replacing the p's by unity in the previous one. It can be seen that in some problems the p's may be replaced by preassigned quantities depending on the risks associated with the misclassification of individuals belonging to various populations.

As an application of this, we may consider three multivariate normal populations with the identical dispersion matrix (α_{ij}) and its inverse (α^{ij}). If m_{ij} represents the mean of the i-th character in the j-th population and $x_1, \ldots, x_p$ are the measurements on an individual, then the following functions can be constructed.

$$L_1 = 2\Sigma(\alpha^{i1}m_{11} + \alpha^{i2}m_{21} + \ldots + \alpha^{ip}m_{p1})x_i - \Sigma\Sigma\, \alpha^{ij}m_{i1}m_{j1}$$

$$L_2 = 2\Sigma(\alpha^{i1}m_{12} + \alpha^{i2}m_{22} + \ldots + \alpha^{ip}m_{p2})x_i - \Sigma\Sigma\, \alpha^{ij}m_{i2}m_{j2}$$

$$L_3 = 2\Sigma(\alpha^{i1}m_{13} + \alpha^{i2}m_{23} + \ldots + \alpha^{ip}m_{p3})x_i - \Sigma\Sigma\, \alpha^{ij}m_{i3}m_{j3}.$$

The individual is assigned to π_1 if $L_1 \nless L_2$, $L_1 \nless L_3$; to π_2 if $L_2 \nless L_3$, $L_2 \nless L_1$; and to π_3 if $L_3 \nless L_1$, $L_3 \nless L_2$. The procedure is similar when more than three populations are involved. If in the above problem the dispersion matrices are not identical, the functions corresponding to the L's will be quadratic in the variables $x_1, \ldots, x_p$.

In some problems it may be necessary to assert with some degree of confidence that an observed individual has arisen from a particular population. In such a case each of the regions R_i may be divided into two mutually exclusive regions R'_i and D_i, so that if the individual falls in R'_i he is taken as belonging to π_i, and if in D_i he is provisionally accepted as belonging to π_i. This latter class may be denoted by π_i ?. The region R'_i may be chosen such that $P(I \subset R'_i \mid \pi_i)$ is maximum subject to the condition that the probability of an individual from any population other than π_i falling in R'_i is $\ngtr$ than a conventionally chosen value (0·05). Applying the calculus of variations one finds that the region R'_i is given by $f_i \geqslant a_1 f_1 + \ldots + a_kf_k$, where $a_1, \ldots, a_k$ are chosen such that $P(I \subset R'_i \mid \pi_i)$ is maximum subject to the condition $P(I \subset R'_i \mid \pi_j)$ for any $j \neq i$ is $\ngtr$ than 0·05. If in some situations the values of $P(I \subset R'_i \mid \pi_j)$ are specified in advance, then the a's can be chosen to satisfy these conditions.

It results in a certain amount of simplification if the region R'_i is defined as $f_i \geqslant A_1 f_1, f_i \geqslant A_2 f_2, \ldots, f_i \geqslant A_k f_k$, where the A's are suitably chosen. This, however, differs from the best region obtained above. The comparative advantages of these regions and their use in the statistical theory of choice of one out of many alternatives will be discussed in a paper to be published elsewhere.

I wish to thank Prof. R. A. Fisher for his valuable advice in the preparation of this note.

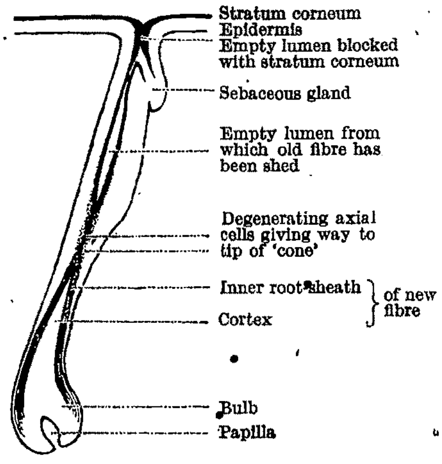
Replacement of Fibres in Sheep

EMPTY follicles, from which the fibres have apparently been shed, have been observed in skin samples from several breeds of sheep of various ages from one month to five years old, namely, Romney, Leicester and Blackface breeds. These skin samples were fixed either in formol saline or in Zenker and stained by a special combination of safranin, alum-carmine and picro-indigocarmine, details of which will be published elsewhere.

Examination of such follicles in horizontal and vertical serial sections has revealed the frequent occurrence of a type of shedding in which the old fibre is lost from the follicle when the new fibre is in the very early stages of its development, so that there is no possibility of the new fibre either growing alongside the old one or mechanically forcing it out, as described in other mammals by Segall[1] and others. In a few instances, a shed 'club-rooted' fibre was observed lying loosely in the distal part of the follicle some distance above the new fibre cone.

A second interesting feature is the occurrence in the follicle, immediately above the level of the tip of the new fibre cone, of an axis of cells histologically corresponding to the granular layer of the epidermis; these are apparently 'canal cells' as described in fœtal follicles in man by Stöhr[2], and also in sheep by Wildman[3]; but they are placed at a lower level in the follicle in our material than in the fœtal material described by Wildman. Segall, on the other hand, denies the presence of 'canal cells' in the guinea pig.



Stratum corneum
Epidermis
Empty lumen blocked with stratum corneum
Sebaceous gland
Empty lumen from which old fibre has been shed
Degenerating axial cells giving way to tip of 'cone'
Inner root sheath
Cortex
of new fibre
Bulb
Papilla

The accompanying diagram illustrates some details of the shedding process just described.

Further work is in progress, in order to determine the frequency and causes of this and other types of fibre-shedding in sheep, and to elucidate the cytological details of shedding and replacement of fibres. Fœtal material prepared in the above way will also be examined for the presence of an axis of granular layer cells in the developing follicles.

New Divisions of Vascular Plants

A WIDELY used classification of vascular plants has recognized four divisions: Psilopsida, Lycopsida, Sphenopsida and Pteropsida[1]. The first three have been erected in the course of time out of Jeffrey's[2,3,5,5a] original Lycopsida. The fourth has not been changed from Jeffrey's[2,4,5,5a] original Pteropsida, and is further subdivided into Filicineæ (ferns) and Spermatophyta (seed plants)—both very large groups. The three divisions and these two subdivisions make five groups of plants widely recognized as distinct groups, though accorded a variety of taxonomic ranks.

Having to teach over the whole range of botany for some years, I have had problems of taxonomy at the higher levels forced on my attention, and for some time have felt a difficulty in expounding the Pteropsida as a coherent group corresponding to the Psilopsida, Lycopsida and Sphenopsida. Our present-day clearer knowledge of meristematic activity at apices, and in the origin of leaf primordia and branch primordia, together with other considerations, has led me to propose that the division Pteropsida be replaced by two divisions, the Filicopsida (ferns) and Spermatopsida (seed plants).

These two divisions may be differentiated as follows.

Filicopsida (the ferns, formerly Filicineæ—see Eames[1]—or Filicales—see Scott[6] and Bower[7]): (*a*) One superficial apical cell or 1–4 uniform superficial apical cells as initiators of structure. (*b*) Primary branching at the apex of the shoot infrequent, prominently dichotomous* and terminal. (*c*) Leaves arise from one or a very few superficial cells and develop superficial apical cells. (*d*) Sporangia of only epidermal origin. (*e*) Dispersed as spores.

Spermatopsida (the seed plants, formerly Spermatophyta—see Rendle[8] and Eames[1]—or Spermophyta—see Scott[6]): (*a*) Differentiated, massive meristem, several layers deep, as initiator of structure. (*b*) Primary branching at the apex of the shoot frequent, lateral and axillary to the leaves. (*c*) Leaves arise by combined activity of a zone of cells several layers deep, and develop a meristem which, if apical, is massive and differentiated. (*d*) Sporangia of essentially hypodermal origin. (*e*) Dispersed as seeds.

Just[9] has put forward a timely plea for observance of the Rules of Botanical Nomenclature in connexion with the major groups of plants. There are great difficulties here as the relevant data are much more complex than for the minor groupings—species, genus, etc. In the above proposal the name Pteropsida was dropped because, among other reasons, *Pteridium aquilinum* appears in Jeffrey's papers[2,4,5] to have no greater claim than many other species, including angiosperms and gymnosperms, to be the type species at the base of a hierarchy of names. I have not attempted to formulate descriptions of the new divisions in set terms, because, though the evidence points clearly to them as good divisions, there is yet more data to be produced anatomically (cf. Dormer[10]), experimentally (cf. Wardlaw[11] and Ball[12]) and bibliographically before we are in a position to do this with assurance of an approach to finality.

This proposal was put before the Botanical Sciences Section of the Sixth Science Congress of the Royal Society of New Zealand, on May 20 of this year. The full statement of the reasons for the proposed change in status and for the choice of names for the new divisions will appear in the published report of the Congress[13]. The present communication is to give a wide and early notice so that those interested may be prepared to receive the proposals with considered criticism.

Aphid Vectors of European Raspberry Viruses

THE failure in vigour and productivity of cultivated raspberries during the last decade in England, and more especially in the concentrated raspberry-growing districts of Scotland, has been due mainly to the spread and cumulative effect of a number of virus diseases. This has been amply demonstrated by the work of Harris[1,2] and our own unpublished work. A precise determination of the viruses concerned and of their interrelations and the development of remedial measures have, however, been severely handicapped by the absence hitherto of information on the natural vectors of the viruses concerned.

Insect transmission of the European raspberry viruses has long been suspected on the basis of evidence from combined field studies of insect fauna and disease spread[3]. Confirmation of these suspicions, provided by data from a series of experiments begun by one of us (C. H. C.) in 1944, is the reason for publishing this note.

The only aphid species of general occurrence on raspberries in Scotland are *Amphorophora rubi* Kalt. and *Aphis idæi* V.d.G. Exploratory experiments carried out in 1944 and 1945 demonstrated that both these species could act as vectors of viruses causing two distinct types of mosaic disease, whereas all attempts to effect transmission by means of jassid and thrips species proved negative. A series of more critical experiments carried out in 1946 have confirmed these findings and provided the data set out in the accompanying table.

Populations of aphids were allowed to feed, for the time intervals stated, on entire plants or, in the case of Series *A*, on detached leaves, of an apparently healthy stock of Lloyd George known to be carrying at least the Mosaic 2 virus or viruses of Harris[2]. The cultures were maintained under muslin sleeve cages from which large numbers of aphids were transferred to each of ten virus-free plants of the indicator variety Norfolk Giant similarly caged. The aphids were allowed to feed on these healthy plants for varying periods, up to 14 days, before being destroyed by fumigation.

Series	Infection feeding time on Lloyd George	Aphid spp.	
		A. rubi	*A. idæi*
A	12 hours	0/10*	0/10
B	3 days	1/10	1/10
C	7 days	2/10	1/10
D	14 days	2/10	2/10
E	21 days	0/10	2/10

* Numerators show numbers of plants infected; denominators show number of plants colonized with aphids.

The experiments were, of necessity, performed in non-insect-proof glasshouses, but, whereas symptoms of mosaic appeared in the indicator plants of Series *C* and *E* 24 days after the date of transfer, no such symptoms developed either on the twenty control plants or on the stock plants upon which the aphid cultures had originally been reared.

With one exception, Norfolk Giant plants on which *Amphorophora rubi* had fed developed symptoms only of Mosaic 2; while the six affected plants in the set of fifty to which *Aphis idæi* was transferred all developed symptoms of a distinct and hitherto undescribed disease provisionally named 'curly dwarf' (Harris and Prentice *in litt.*). The exceptional plant in the *A. rubi* series also developed curly dwarf. The presence, in the Lloyd George infector stock, of the viruses causing these diseases has since been confirmed by grafting to indicator hosts.

The results suggest that both aphid species require feeding periods longer than twelve hours to pick up the viruses causing these distinct symptoms, and also that at least *Aphis idæi* shows a marked degree of specificity in the viruses transmitted. The design of the experiments does not permit of any further deductions on the relations between the aphid vectors and the viruses they transmit.

So far, transmission has been achieved with difficulty; very large numbers of aphids have been employed except in the case of a subsidiary experiment using seedling plants raised from a Norfolk Giant × St. Walfried cross, where transmission of Mosaic 2 by *Amphorophora rubi* was effected by 25–50 aphids per plant. This finding is, however, in conformity with the slow rate of spread of mosaic diseases under field conditions.

A fuller account of these and cognate investigations will be published at a later date. The evidence here set out does, however, permit the conclusion that the common raspberry aphids, *Amphorophora rubi* Kalt. and *Aphis idæi* V.d.G. are capable of acting as vectors of certain raspberry viruses under Scottish conditions.

The investigation, of which this work forms a part, is financed by a grant from the Agricultural Research Council, to which our acknowledgments are therefore due.

Optimum pH and Temperature, and Energy of Activation of the Transamination between Glutamic Acid and Pyruvic Acid

In a previous paper[1] I stated that the process:

$$\text{glutamic acid} + \text{pyruvic acid} \underset{b}{\overset{a}{\rightleftharpoons}} \alpha\text{-ketoglutaric acid} + \text{alanine} \quad . \; . \; . \; . \; . \; (1)$$

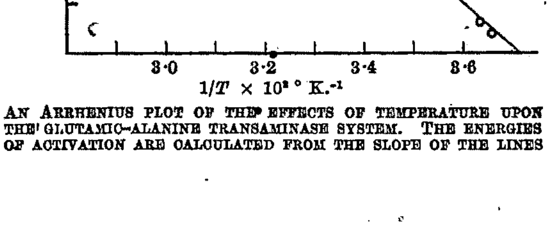
reaches an equilibrium through a first-order reaction according to the equation:

$$\log_e (1 - \alpha/\alpha_0) = -kt.$$

In this, k is the velocity coefficient, t the time measured in seconds, α the degree of reaction at the time t, and α_0 at the time $t = \infty$, when the equilibrium has been attained. In the temperature interval 15°–70° and at pH 7·5, $\alpha_0 = 0 \cdot 60$ for reaction (1a) and $\alpha_0 = 0 \cdot 40$ for (1b).

Using k as a measure of the strength of the enzyme (alanine–glutamic transaminase), it is possible to determine in an absolutely unambiguous way the relation between enzyme activity and pH or temperature.

The enzyme was prepared by extraction of minced ox hearts with 1/15 M phosphate buffer (pH 7·5). The liquid is pressed through a linen cloth and half saturated with ammonium sulphate. The precipitate containing the enzyme is filtered off, suspended in water and dialysed in a 'Cellophane' tube against running tap water. The undissolved residuum is centrifuged off and discarded. The solution is heated at 60° for 10 min. The heat-coagulated protein is centrifuged off and the clear supernatant liquid is used in what follows. The determination of k is carried out as previously described[1]. The concentration of substrate in the reaction mixture (enzyme + substrate + buffer) is 0·0167 M with regard to amino- and keto-acids.



An Arrhenius plot of the effects of temperature upon the glutamic–alanine transaminase system. The energies of activation are calculated from the slope of the lines

Using k as a measure of the enzyme strength, it appears that the reaction has a maximum of velocity at pH 7·5 in accordance with Kritzmann's result[2]. The velocity is very sensitive to changes in pH; altering pH from 7 to 7·5 increases k about threefold. In a similar manner the optimum temperature is found to be 75° C. In order to decide whether the enzyme reaction follows the Arrhenius equation, $\log_e k \times 10^5$ is plotted against the reciprocal absolute temperature ($1/T \times 10^3$) as shown in the accompanying graph. A sharp break in the relationship occurs at 34°. It is apparent that the reaction follows the Arrhenius equation accurately from 0° to 34° with an energy of activation of 17,475 cal., and from 34° to 70° with an energy of activation of 8,740 cal. Such a shift at a critical temperature has been reported previously with regard to other enzyme systems[3].

The energy of activation and Q_{10} for the alanine–glutamic transaminase system as reported by me earlier[1] is no longer relevant, as the temperature interval in which the two constants are computed (25–35°) includes the critical temperature.

Visual Cells of the Guinea Pig

O'Day has pointed out[1] that his histological preparations provide definite evidence for the presence of cones in the retina of the guinea pig. I welcome this statement, although I have myself, as he indicated, relied on authors who have denied it. Occasionally one finds evidence for red modulators in the eye of the guinea pig (see, for example, Fig. 140, p. 281, of my recent summary[2]). Such modulators, I maintain, should be ascribed to cones if the histological differentiation of the cells into rods and cones is going to mean anything at all to retinal physiology. There are more of them in the eye of the rat. Since, however, some histologists deny the presence of cones in the eye of the rat (see ref. 2), and others refuse to accept them in the guinea pig, the physiologist must try to stand on his own feet.

I have suggested[2] that the red modulators in the eye of the rat are due to cones. But cones cannot be as important in the eyes of the guinea pig and the rat as in the retina of the cat. The latter has a very much greater number of the on/off-elements typical for cones (80 per cent); at least 36 per cent of the elements show a complete Purkinje shift with light adaptation. I have never found such Purkinje shifts in the eyes of rats and guinea pigs[2].

ROYAL SOCIETY MEDAL AWARDS, 1947

THE following is the substance of the remarks made by Sir Robert Robinson, president of the Royal Society, in presenting the medal awards for 1947 at the anniversary meeting on December 1.

Copley Medal

The Copley Medal is awarded to Emeritus Prof. G. H. Hardy in recognition of his distinguished contributions to mathematics [died December 1].

For many years G. H. Hardy has occupied an outstanding position among mathematicians in Great Britain, while his eminent services and original work have also been very widely recognized in other countries. In his memoirs and papers published with collaborators, especially J. E. Littlewood, are to be found the origins of the major developments of 'classical analysis' throughout the world in the years 1910–35.

Among the most influential and original of his works are those dealing with the Tauberian theorem for Cesàro summability (1910); the proof that the Riemann zeta-function has an infinity of zeros on the critical line (1914); the asymptotic formula for the number of partitions of an integer (with Ramanujan, 1918); the papers on Waring's problem and Goldbach's problem (with Littlewood, 1920, 1922); the paper in *Acta Mathematica* on Fourier series (with Littlewood, 1930). He has made important contributions to lattice-point theory, to the theory of integral equations, and (with Littlewood) to the theory of Diophantine approximation.

Lying in widely separated domains of analysis, all these papers contain fundamentally novel ideas which were the starting-points for new significant developments by Hardy and others. For example, a part of the distinguished work of Vinogradoff may justly be said to derive from that of Hardy. His influence has been exerted, not only by his publication of original work, but also through a long succession of pupils, many of whom are now well-known mathematicians. At a time when the vigorous treatment of analysis in university courses had still to win general acceptance, Hardy's enthusiastic advocacy and his inspiring lectures had a decisive effect. In addition, the appearance of his highly individual text-book "Pure Mathematics", helped to demolish finally the barriers between the British and Continental schools of mathematics.

It is impossible to characterize in a few sentences the achievement, so varied, and so abstruse, of the Copley Medallist for 1947, but in very ordinary words it may be said that Hardy saw clearly what were the most important tasks and problems lying before mathematicians; he had good judgment in selecting those which seemed ripe for attack, and he displayed the greatest skill and energy in their solution.

Royal Medals

A Royal Medal is awarded to Prof. C. N. Hinshelwood, for his outstanding researches in chemical kinetics.

Prof. Hinshelwood has brought a characteristic lucidity of mind and directness of approach to bear on the investigation of many classical problems presented by the course of chemical change. He has clarified these subjects to an extent which seems remarkable to those who recall the mystery which enshrouded them only a few years ago.

The acute suggestion of Lord Cherwell relating to the consequences flowing from the relative rates of formation and decomposition of an intermediate additive complex was taken up and extended by Hinshelwood. He predicted that on the basis of this theory certain apparently monomolecular reactions should follow a bimolecular law at low pressures. One example of the justification of this prophecy was found in the decomposition of acetaldehyde. This experimental verification of the hypothesis of intermediate complexes of definite life, and the new light shed on the mechanism of activation of molecules, are pillars of modern chemical kinetics. Hinshelwood has enlarged our knowledge of this subject by many other researches of great importance including those on the synthesis of water, a classical problem of seeming simplicity and real complexity, and those on the conditions of 'chain' reactions. His ingenious experimental methods, though characterized by a lack of unnecessary elaborations, have nevertheless always been able to provide accurate results.

It was a very original conception to apply the principles and methods of chemical kinetics to the growth of bacteria, and Hinshelwood has already made noteworthy progress in this field. The outcome has been to provide a new and more delicate assessment of the presence and activity of factors that influence growth at all stages under defined conditions.

During the War he carried out important researches on the adsorption of gases by charcoal, and on the preparation of suitable adsorbents for different purposes, ranging from gas-masks to the production of penicillin.

The brilliant exposition of chemical topics contained in Prof. Hinshelwood's books places contemporary chemists and students still further in his debt. His memorable addresses on the wider implications of chemistry made as president of the Chemical Society and on the occasion of the celebration of its centenary were generally acclaimed. Possessing enviable linguistic attainments, he has frequently been an 'ambassador of British science'. Recognizing these achievements we wish to honour Prof. Hinshelwood above all for his pioneering work in the laboratory and in the study, which has thrown so much light on the most fundamental processes of chemistry, the mode of interaction of molecules.

A Royal Medal is awarded to Dr. F. M. Burnet for his distinguished contributions to our knowledge of the viruses.

Dr. Burnet, director of the Walter and Eliza Hall Institute, at Melbourne, has made a series of extremely significant investigations of bacteriophages and viruses since 1925. In twenty-seven papers on the first topic he has made greater advances than anyone apart from d'Herelle. He has elucidated the phenomenon of lysogenesis or 'carrying' of a bacteriophage, active against other bacteria, by an organism which is itself apparently unaffected. He has shown how study, partly on a biochemical basis, of the range of activity of 'phages against various bacteria can be used to classify not only the 'phages but also the bacteria themselves. Other investigations have made an important contribution to our present ideas as to what bacteriophages are.

Since 1933 he has studied many viruses pathogenic for vertebrates. He has shown how psittacosis is endemic in wild Australian parrots, and has thrown light on the epidemiology of herpes and poliomyelitis. To modern workers he is best known for his development of several techniques for cultivating viruses in living chick embryos, and their application in immunological and other studies of viruses, especially influenza. He has written monographs on the use of chick embryos in virus research, on immunity to viruses, on influenza and on the nature of antibodies.

At present he is examining the agglutination of mammalian and avian red blood cells by a number of viruses and virus-products, and is thus throwing fresh light on the reactions taking place between viruses and the surfaces of susceptible cells. He has found that an enzyme produced by cholera vibrios has an action on blood cells which is quite similar to that of influenza viruses, and is capable of blocking the union between virus and susceptible cell. This discovery indicates one line of approach to the problem of the chemotherapy or chemoprophylaxis of virus infections.

Burnet has been active in many other fields; he has studied staphylococcal toxins and he was the first to make a formolized staphylococcal toxoid. He has demonstrated that a rickettsia is the cause of Australian *Q*-fever.

While his experimental studies have demanded close attention to detail, certain continuous threads have connected his interests. The breadth of his outlook and his philosophic attitude of mind are well exemplified in his fascinating book "Biological Aspects of Infectious Diseases" and in the more recent publication "Viruses as Organisms".

Davy Medal

The Davy Medal is awarded to Prof. Linus Pauling in recognition of his distinguished researches on molecular structure.

The unusual breadth of Prof. Pauling's scientific knowledge, his mastery of physics and mathematics in addition to chemistry, made him peculiarly fitted to apply quantum mechanics to problems of chemical valency bonds. In him, theoretical acumen and penetrating insight are associated with experimental skill of the highest order, and thus his theories were often tested after the devising of new physical techniques. This combination of theoretical and practical attainments is very remarkable at such a level in both aspects.

As a natural consequence of his catholic interests, Pauling's work has covered a very wide range of chemical structural problems. He has devoted much attention to line spectra and many other physical topics; but his most individual achievements are in the advance of molecular structure theory. In elucidating the fundamental structure of simple organic compounds he developed the method of localized pairs (atomic orbitals) to provide a theoretical treatment of the valency conditions of such molecules. By this introduction of orbital hybridization he gave the first theoretical account of the tetrahedral distribution of the valencies of the saturated carbon atom (1928). This was followed by the introduction of the quantum mechanical concept that the actual state of a molecule such as benzene should be represented as a resonance hybrid of several valency bond structures (1931). The application of this idea and the experimental verification of its structural implications in terms of increased stability and decreased bond distances greatly increased our understanding of aromatic and general chemistry. The calculus of the resonance theory of Pauling was the first to introduce a quantitative treatment of valency problems, and its effect has been felt far beyond the bounds of the experimental material.

In 1939 his extensive work was summarized in a great book "The Nature of the Chemical Bond", which will always be one of the classics of chemistry. Here we find a general classification of stubborn aspects of valency theory along with valuable tables of generalized and correlated data on resonance energy terms, bond distances and angles, and atomic radii.

Proceeding to apply his methods to the study of more complex molecular systems, Pauling has made important contributions to our understanding of the metallic bond; of the structure and mode of denaturation of native proteins; and of the mechanism of the fundamental reactions of immunology, that is, antibody formation, and the antibody–antigen interaction.

Prof. Pauling has earned our gratitude, not only for his personal services, great as those have been, but also because he has been a focus of activity and a constant source of inspiration to other workers.

Buchanan Medal

The Buchanan Medal is awarded to Sir Edward Mellanby for his services to medical science and in recognition of his outstanding researches on dietary factors.

The Buchanan Medal is awarded every five years in respect of distinguished services to the science or practice of hygiene in the direction either of original research, or of professional, administrative, or constructive work, without limit of sex or nationality. In each of these respects the award to Sir Edward Mellanby is surely one of the most appropriate that could be made. For some thirteen years he has devoted himself to the service of medical science and the national organisation of medical research. His personal research work, which has been continued right up to the present time, has been concerned mainly with problems of nutrition, and has had important results in the relation of diet to the public health.

Sir Edward's two most important contributions have been on the effects of deficiency of vitamin D and of vitamin A in the diet. He first showed that rickets was unquestionably due to the lack of a fat-soluble vitamin, since known as vitamin D, and he also demonstrated that other factors, dietary and general, such as lack of exercise, contributed to aggravate the condition. Quite recently he has shown that lack of vitamin A, in addition to the already recognized effects on general health, is capable of producing profound neurological disorders, owing to the mechanical effect of abnormal growth of bones around the foramina through which nerves leave the central nervous system. The knowledge which has been made available as a result of his investigations has played an important part in the feeding of the nation on scientific lines, in war, and in peace-time.

The study which he made of the effects of lack of iodine has thrown much light on the various forms of goitre, and especially on the hyperplastic and colloid forms: the former he showed to be caused by iodine deficiency, particularly in young animals, or in ante-natal states, while the latter is produced by the belated admission of iodine to such sufferers from the hyperplastic condition. The knowledge has been of value in connexion with the lack of iodine in the water and soil of some districts.

Mellanby's researches on the physiological effects of alcohol have also provided valuable knowledge concerning the effects of this substance as a constituent of the diet.

His most recent contribution has been to show that bread which is made from flour bleached by the 'Agene' process, that is, with nitrogen trichloride, can cause the condition in dogs known as canine hysteria.

As the secretary of the Medical Research Council, Sir Edward has proved himself a wise, strong and withal a helpful administrator.

Hughes Medal

The Hughes Medal is awarded to Prof. J. F. Joliot in recognition of his outstanding researches in nuclear chemistry and physics.

Prof. Joliot, director of the Nuclear Chemistry Laboratory of the Collège de France, was early concerned with investigations leading to the discovery of the neutron and with subsequent work on that particle. In 1932 he found that the very penetrating radiation emitted when beryllium is bombarded with alpha-particles was able to eject protons from hydrogenous material upon which it fell. This observation was followed up by Chadwick, who was able to show that the radiation consisted of the neutrons which he and Rutherford had sought for years.

In 1934 Joliot made a discovery of the utmost importance. He found that aluminium and other light-atom substances were rendered radioactive by bombarding them with alpha-particles. He showed that these radioactive products emitted positive or negative electrons and gamma-rays. By chemical methods he proved that the radioactivity produced was due to the formation of unstable isotopes of neighbouring elements; for example, in the case of aluminium, the active substance produced was an isotope of phosphorus. It was soon shown that the production of these artificially radioactive isotopes was possible by bombardment with other types of particle and that practically all the elements could be prepared in radioactive form. In this way Joliot founded an important development of modern 'tracer' technique and opened up a field of investigation of immense importance to physical, chemical, and biological science.

In 1939 Joliot and his co-workers observed that in the process of fission of uranium several neutrons are emitted. This important observation indicated the possibility of a chain process in uranium, and Joliot at once endeavoured to produce such a self-propagating reaction. With Halban and Kowarski he showed, in 1940, that if the fission neutrons were slowed down in heavy water a chain-reacting system could be produced. The practical success of the heavy-water 'piles' in the United States of America and in Canada is the outcome of these pioneering discoveries in the application of atomic energy.

In a great part of his work, Prof. Joliot has been closely associated with his wife, Prof. Irène Joliot-Curie.

SYNTHESIS OF PHOSPHOLIPIDS IN THE FŒTUS

By G. POPJÁK

Beit Memorial Fellow for Medical Research,
St. Thomas's Hospital Medical School, London

WHETHER fœtal lipids are derived primarily from the preformed maternal substances by placental transmission, or from synthesis within the fœtus, cannot yet be answered satisfactorily. Up to now, most investigators have been concerned with the placental transmission of fatty (and other) substances, and very little has been done to explore the possibility of synthesis of these compounds by the fœtus. Nielson[1] studied the permeability of the rat placenta to phospholipids with the aid of P^{32} and found that after the injection of the mother with inorganic phosphate, labelled with P^{32}, radioactive phospholipids could be isolated from the fœtuses within 2 hr. after the injection. When, on the other hand, an emulsion of phospholipids labelled with P^{32} was injected intravenously to the mother, the appearance of radioactive phospholipids in the fœtuses was very much delayed, and even then only small amounts were found. Nielson, therefore, concluded that the placenta does not transmit phospholipids and that these substances are readily synthesized within the fœtus. In my experience, when an emulsion of phospholipids is injected intravenously, so long as any of the excess phospholipid remains in the circulation, it always stays in the form of an emulsion. The only conclusion, therefore, that can be drawn from Nielson's work is that the placenta does not transmit emulsions of phospholipids; whether this is also true for the plasma phospholipids in the physiological state of dispersion remains an open question. In order to follow the experimental design of Nielson in the investigation of the sources of fœtal phospholipids, the mothers should be transfused with plasma containing labelled phospholipids. Up to now, the supplies of P^{32} in Great Britain have been small, and therefore this experiment, requiring relatively large amounts of the isotope, is not practicable.

There is, however, another possible way of attacking this problem. After the injection of a suitable dose of P^{32} in an inorganic form, the plasma phospholipids become labelled with this isotope. If fœtal phospholipids are derived from the preformed maternal substances only, then the radioactivity of fœtal phospholipids should never exceed the activity of the maternal plasma phospholipids. If, on the other hand, a rapid synthesis takes place within the fœtus, and if the transfer of inorganic phosphate from the mother to the fœtus is sufficiently rapid, then there might conceivably be a time when the activity of the fœtal phospholipids is greater than the activity of the maternal plasma phospholipids.

Pregnant rats, guinea pigs and rabbits were injected subcutaneously or intravenously with disodium hydrogen phosphate labelled with P^{32}. After varying intervals, the phospholipids were isolated from the maternal plasma, maternal liver, fœtal liver, fœtal carcass and viscera, fœtal placenta, and whenever possible from the fœtal plasma also, and their radioactivities compared. In several experiments, the inorganic phosphate of the tissues was precipitated as the ammonium-magnesium salt from a trichloracetic acid extract and its radioactivity measured

TABLE 1. RADIOACTIVITY OF TISSUE INORGANIC-P AND OF PHOSPHOLIPID-P RELATIVE TO THAT OF MATERNAL PLASMA PHOSPHOLIPID-P

Rabbit 138: 3·16 kgm., 26th day pregnancy, 4 hr. after intravenous injection of a single dose of P^{32} as Na_2HPO_4

Source	Specific activity in relative units	Activity of liver phospholipid-P as % of activity of tissue inorganic-P
Maternal plasma phospholipid-P	100	—
Maternal liver inorganic-P at the end of experiment	2570	—
Maternal liver phospholipid-P	405	15·76
Fœtal liver inorganic-P at the end of experiment	1098	—
Fœtal liver phospholipid-P	221	20·10
Fœtal placenta phospholipid-P	328	—
Fœtal plasma phospholipid-P	39·6	—
Fœtal carcass (without liver) phospholipid-P	45·3	—

also. The measurements of radioactivity were carried out with a Geiger-Müller counter.

The results were alike in all three species, and because more detailed experiments were carried out with rabbits, results of representative experiments obtained on this animal alone are shown. From Table 1 it is evident that the activity of the phospholipids extracted from the fœtal liver and fœtal placenta was much greater than the activity of the maternal plasma-phospholipids 4 hours after the injection of the mother with labelled phosphate. These two fœtal organs, therefore, appear to be sites of phospholipid synthesis. The activity of the fœtal carcass- and plasma-phospholipids, on the other hand, was much less than the activity of the maternal plasma phospholipids; and therefore it cannot definitely be decided from this and similar experiments whether these phospholipids were synthesized within the fœtus or derived from the mother by placental transmission. The low specific activity of the fœtal plasma phospholipids shows that the highly active lipids in the fœtal liver have been synthesized in that organ, and have not been transported from the fœtal placenta.

The observed radioactivity of phospholipids extracted from the tissues, after the injection of labelled phosphate into an animal, depends not only on the rate of synthesis of the lipid, but also on the abundance of the isotope in the inorganic phosphate fraction of the tissues. In the experiment shown in Table 1, the activity of the maternal liver phospholipid phosphorus was 15·76 per cent and that of the fœtal liver phospholipid phosphorus 20·1 per cent of the activity of the inorganic phosphorus in these organs. There are reasons to believe that this difference indicates that the rate of phospholipid synthesis is higher in the fœtal than in the maternal liver, the most active adult organ in this respect.

TABLE 2. RELATIVE SPECIFIC ACTIVITIES OF PLASMA- AND TISSUE-INORGANIC-P AND PHOSPHOLIPID-P IN MOTHER AND FŒTUS

Rabbit 148: 3·5 kgm., 24th day pregnancy. The radioactivity of maternal plasma-inorganic-P was maintained constant (to within ± 10 per cent) for 250 minutes by the repeated subcutaneous injection of P^{32} at 20–30 min. intervals

Source	Specific activity of Inorganic-P	Specific activity of Phospholipid-P	Activity of tissue phospholipid-P as % of activity of inorganic-P in the tissues
Maternal plasma	100	0·945	—
Maternal liver	30·72	2·48	8·07
Fœtal plasma	62·9	—	—
Fœtal liver	20·2	2·64	13·08
Fœtal carcass (without liver)	7·14	0·50	7·02
Fœtal brain	1·85	0·147	7·95
Fœtal placenta	30·65	4·34	14·20

In Table 2, results of a more detailed experiment are shown. The activity of the maternal plasma inorganic phosphorus was maintained constant for 250 min. The figures in this table give further emphasis to what has already been said (compare activities of phospholipids) and show, in addition, that the probable reason for the low activities of fœtal carcass- and brain-phospholipids is that the concentration of the isotope in the inorganic phosphate fraction in these tissues was very low. The activities of the fœtal carcass- and brain-phospholipid phosphorus were 7·02 and 7·95 per cent respectively of the inorganic phosphorus in these tissues; values not much lower than the figure for the maternal liver (8·07 per cent). These figures suggest by themselves that there is synthesis in these tissues also, at a rate comparable with that in the maternal liver.

TABLE 3. RELATIVE ACTIVITIES OF FŒTAL PHOSPHOLIPIDS 3 HR. AND 3 HR. 10 MIN. AFTER INJECTION OF LABELLED Na_2HPO_4 INTO RABBIT FŒTUSES 25 DAYS OLD

Rabbits 151 and 152

Source of phospholipids	Specific activity of phospholipids: 3 hr. after injection	Specific activity of phospholipids: 3 hr. 10 min. after injection
Maternal plasma	Inactive*	Inactive*
Fœtal liver	100	100
Fœtal viscera (intestines, kidneys, lungs and heart)	—	39·1
Fœtal carcass (without liver)	17	—
Fœtal brain	3·34	3·84

* That is, no activity could be detected in phospholipids that could be extracted from 15 ml. of plasma.

That phospholipid synthesis is taking place in all fœtal tissues was proved definitely by experiments in which the fœtuses were injected directly *in utero* with disodium hydrogen phosphate labelled with P^{32}. The mothers were given nembutal (three quarters full anæsthetic dose) and for the actual operation the anæsthesia was deepened with ether; after opening the abdomen, the labelled phosphate was injected with a fine needle through the uterine wall into the back of the fœtus. The abdominal incision was then closed. The experiments lasted 1–3 hr.; results of two are shown in Table 3. The fœtuses suffered no apparent ill-effects either from the injection or from the operation on the mother. By this technique it was possible to obtain high activities in the fœtuses and very low activities in the mother. In one experiment, for example, the inorganic phosphorus in 0·1 ml. of fœtal plasma gave 500 counts/min. and the same volume of maternal plasma, withdrawn at the same time, only 5 counts/min. above background. It is evident from Table 3 that the fœtal tissues examined all synthesize phospholipids. When the activity of the phospholipids in these experiments is expressed as a percentage of the activities of the inorganic phosphorus in the tissues, values are obtained which are comparable with those in experiments of the type illustrated in Table 2. This makes it highly probable that all fœtal phospholipids are synthesized within the fœtus.

The evidence presented, of course, indicates only that the phosphorylating step in phospholipid synthesis takes place in fœtal tissues, and it remains to be seen whether the other steps required in building up whole phospholipid molecules also occur.

---

CLASSIFICATION, BREEDING AND PRESERVATION OF THE POTATO

A SYMPOSIUM, at which recent investigations on the classification, breeding and preservation of the potato were discussed, was arranged by the Association of Applied Biologists and held in London on October 3.

The South American potatoes, their classification, affinities and value to the potato breeder were discussed by J. G. Hawkes. It was pointed out that breeders are turning more to the indigenous potatoes of the American continent in their attempts to solve problems of disease resistance and adaptation to new environments. The co-operation of the systematist, the cytologist and the geneticist is needed when dealing with the transference of the useful properties from the wild potatoes to the domestic varieties.

Mention was made of the potato-collecting expeditions in South America and especially of the British Empire Expedition sent out by the Imperial Agricultural Bureaux in 1939. An outline was given of the collection brought back by this latter expedition and the work in progress at the Empire Potato Station at Cambridge. Its use in conjunction with Empire potato breeders was also discussed. The distribution of the wild potatoes and their varied type of habitat indicate their possible use in breeding new varieties suited to climates where the potato of commerce will not at present grow.

An outline followed of the method of classification of the wild species into groups, and the valuable economic characters to be found among them. Resistance to blight, frost, viruses and Colorado beetle, together with a form of immunity to potato root eelworm, are to be found among the wild species. Some cultivated potato species are frost-resistant; others possess a very short dormancy and ability to grow at higher temperatures; others, again, are promising in respect of vitamin C and protein contents.

Many of the valuable characters are to be found in potatoes only distantly related to the cultivated varieties of Europe. Studies on chromosome numbers and on the 'crossability' of the various species are giving more exact information on their relationships and helping in the transference of the valuable disease resistance from the wild potatoes into our domestic varieties.

W. Black dealt with blight in potato breeding. Potato seedlings bred from the immune wild species *Solanum demissum* have been tested for resistance to the common strain of blight, A, and two new strains, B and C. Although B and C are more virulent than A, they differ qualitatively from each other. A fourth strain, D, appears to be slightly less virulent than C and to differ from it quantitatively. The fungus is considered to exhibit plasticity and it is thought that its virulence can be built up or modified by the degree of resistance of the host plants on which it is grown.

Studies on the inheritance of resistance indicate that, with the A, B and C strains, blight resistance behaves as a dominant, appearing to be controlled by four major genes, Ra, Rb, Rc and R_3, conferring immunity from strain A, B, C and all three respectively. It is also considered that minor genes may be present which act as modifiers in the resistant varieties and determine the degree of susceptibility in the susceptible varieties. In genetical studies the ratios obtained always show an excess of recessives. This is thought to be due either to chromosome homologies leading to multivalent production, or more probably to the presence of incompatibility factors contributed from the wild parent.

Tests were described for ascertaining the genetical constitution with regard to blight immunity in parent varieties, and evidence was presented that suggested an increase in the virulence of the B strain of blight.

In the afternoon session, A. R. Wilson spoke on methods of potato storage in North America, basing his remarks on information gained during a tour under the auspices of the Agricultural Research Council in consultation with the Department for Scientific and Industrial Research and the National Farmers' Union.

Various types of storage building were described, ranging from an ordinary farm basement to a refrigerated and air-conditioned store built specially for the purpose. Partially or completely sunk stores, depending for their heat insulation chiefly on the soil banking around them, are capable of several modifications. Some are of the deep bin type with bins 18–25 ft. deep—to be found chiefly in the colder areas—whereas others are of the shallow (8–12 ft.) bin type found in the warmer areas.

Surface stores, usually of the shallow bin type, are heavily insulated, especially on the roof, to prevent sudden fluctuations of temperature and water condensation with consequent dripping on to the tubers. Various types of bins with different methods of partitioning and detachable front boards for unloading were detailed.

Ventilation and air circulation seem to be very variable in these stores, and are either of the gravity or of the forced-draught type, with the air circulating through the potatoes or passing in the floor, back and sides of the bins—the so-called 'shell' type. On the evidence available, it would appear that the shell type is the slower though more thorough method of cooling. Methods of bulk transport and of temperature control were treated also. Permanent storage accommodation has a future in Great Britain, but the American methods need careful trial here before they are adopted.

A survey of Scottish seed tuber problems was given by C. E. Foister, dealing chiefly with the methods used in attempting to reduce tuber diseases. Mention was made of the certification scheme, which distinguishes three grades for freedom from virus and trueness to type. A registration scheme is also in force to stimulate the production of varieties immune or resistant to disease. Stress was laid on methods of handling potatoes; it is thought that most farmers pay insufficient attention to dressing out diseases and abnormalities in the tubers before dispatch.

The potato work at the Seed Testing Station at Corstorphine was outlined, and the tests for blight resistance on seedlings raised by private breeders were mentioned. It is believed that there is approximately a 75 per cent correlation between foliage and tuber resistance to blight. The co-operative scheme of dry-rot investigations was also mentioned. Since there are no immune varieties at present known, it is hoped that resistance to dry-rot may be found among the South American potatoes in the Empire Potato Collection. Similarly, no varieties immune to skin spot or to scab are known in Britain, and here again the Empire Potato Collection may prove of value.

Mention was made also of black-leg, blind tuber, and a possible outbreak of potato stem eelworm in Scotland this year.

A. E. W. Boyd described some recent results of dry-rot research, indicating the very severe losses in the variety Doon Star with this disease, and the enormous decrease in the acreage grown during the last few years. It was pointed out that dry-rot is caused by the wound parasite *Fusarium cœruleum*, and that the degree of infection is directly proportional to the percentage of wounding. The parasite can also enter through lesions of powdery scab. Rough handling of the potato bags and riddling of the tubers has a very marked effect in increasing the incidence of the disease, and road transport also increases infection with previously riddled tubers.

Methods of control were dealt with in some detail. Dipping in an organic mercury preparation or 1 per cent formalin gives a good measure of control if done at lifting time, though the disadvantages of wet treatments at the busy harvest season are obvious. Thymol at the rate of 5–6 oz. (made up to 10 lb. with kaolin) per ton of potatoes has been found to be the best all-round method of control. Occasionally, however, the thymol exhibits a marked phytocidal effect on the tubers, though generally only a part of each tuber is damaged and the remainder can grow and yield normally. Application of thymol both at lifting and riddling was recommended, since these are the times of maximum damage when infection generally takes place. In the discussion which followed, the merits of the proprietary compound 'Fusarex' were discussed, together with its advantage in delaying sprouting.

J. G. Hawkes

RHEOLOGY OF MINERALS

ANNUAL CONFERENCE OF THE BRITISH RHEOLOGISTS' CLUB

THE annual conference of the British Rheologists' Club was held at Hulme Hall, University of Manchester, during September 11–13. The inaugural address was given by Prof. Harold Jeffreys, of Cambridge, who spoke on the strength of the earth; Dr. Markus Reiner, of Jerusalem, was in the chair. Prof. Jeffreys pointed out that in geophysics it is usual, as a first approximation, to assume that most of the earth is a perfectly elastic solid (transverse elastic waves from earthquakes travel freely through it to a depth of nearly half the radius, corresponding to five-sixths of the volume). Decisive evidence was given that the earth is strongly condensed towards the centre, which consists probably of liquid iron. Prof. Jeffreys discussed geological strains associated with fracture and continuous flow, and spoke on experimental work done on the behaviour of rocks under large stresses. The effective rigidity can be reduced to a half by long loading; but the fact that the Pyramids still stand is evidence that the strain tends to a finite limit. Treating the problem of fracture by dynamical methods, it can be shown that fracture can occur under the pressures existing at 650 km., the deepest earthquake focus recorded, a fact against the many theories that postulate a finite viscosity under stress differences however small. The crushing strengths of granite and basalt, as measured in the laboratory, are about 10^9 dynes/cm.^{2}. Sir George Darwin, studying a harmonic distribution of load resembling a set of parallel mountain chains, found that the stress difference would reach a maximum at a depth $\frac{1}{2}\pi$ of the wave-length and be equal to e^{-1} times the range of load; for the Himalayas, this would suggest stress differences of the order of 10^9 dynes/cm.^{2}, and the great ocean deeps could be supported by similar strengths. It is known that there are widespread disturbances of gravitational fields that are not noticeably correlated with height; these imply genuine variations of mass per unit area, and therefore of load on the lower layer, which cannot be in a hydrostatic state.

A paper on the mechanical properties of soils and their relation to engineering practice was read by A. W. Skempton, University reader in soil mechanics and assistant professor at the Imperial College of Science and Technology, London. The mechanical properties of sands, gravels, silts and clays—referred to as soils in civil engineering—are of importance in many practical problems, including foundations, earth dams, retaining walls, roads and runways. An analysis of many practical problems was given, together with a quantitative description of the main classes of soils. This was followed by an outline of our present knowledge on the shear strength characteristics, with particular reference to clays, and the various problems in which shear strength plays an essential part. The consolidation of clays was also considered, together with some of the results which have been obtained in recent researches on the electro-physical properties of clays and silts.

In the morning session of September 12, Prof. Jeffreys in the chair, papers were read by Prof. F. C. Phillips, Herdman professor of geology in the University of Liverpool, on preferred orientation of minerals and the mechanism of rock flow, and by Dr. G. M. Lees, chief geologist, Anglo-Iranian Oil Co., Ltd., on the formation of salt domes and the flowage of rock salt. Prof. Phillips in his paper pointed out that the primary flow of igneous rocks, consolidating from a melt, may frequently be traced in a linear or platy parallelism of phenocrysts or included fragments in flow layers. Unconsolidated sediments, too, may show primary flow structures in the sense that they may flow by reason of their high water content. Rocks are found folded to a degree varying from gentle flexures to the recumbent overfolds, or nappes, of mountain systems, such as the Alps, with amplitudes of many miles; these have responded to compressional stress by flowing in the sense that they have acquired a permanent deformation without loss of cohesion. Prof. Phillips discussed in detail the actual means by which rock flow is achieved, and gave evidence of dimensional and lattice orientation of individual fabric elements. The fabric of fine-grained rocks such as slates can be studied suitably by X-ray methods. The fact that in most deformed rocks some degree of preferred orientation is present suggests that at some stage a new mechanism of translation gliding operates which allows further deformation without continued rotation. This movement is similar to that in glacier motion and has been ascribed variously to the displacement of rigid masses along shear planes, to local melting and regelation, to intergranular movement and to translation gliding of the crystals.

There is good evidence for translation gliding in minerals such as mica, and twin-gliding in calcite, but there is still no certain evidence of the real mechanism by which the apparent plasticity of quartz is achieved; an artificial orientated quartz fabric has been obtained by shearing according to Larsen and Bridgman.

Dr. G. M. Lees in his paper continued the subject of rock flow by referring to the formation of salt domes in Persia. He illustrated his talk with numerous diagrams of geological sections of the Persian oilfields showing sinuous anticlines 100–200 miles in width, bent and folded with little fracture or faulting although the folds of limestone are 2,000 ft. thick. There was considerable discussion on the mechanism of flow in the salt masses.

There were two papers on viscometry: one by Dr. R. Schnurmann, chief physicist, Manchester Oil Refinery, Ltd., on the effect of shearing stress on the viscosity–temperature dependence of lubricating and hydraulic oils; and another, on industrial viscometers, by Dr. E. W. J. Mardles and Mr. A. G. Ward, speaking on behalf of the committee of the British Rheologists' Club in its report on the subject. Dr. Schnurmann described in detail recent experiments at high rates of shear on the shear breakdown of polymer solutions, the degradation being traced to the fissure of long-chain molecules by mechanical means. In the Committee's report on industrial viscometry, a short survey of conditions of rheological measurements, of methods and of viscometers, penetrometers, etc., was made. The principles which should govern routine measurements for non-Newtonian systems were given briefly, and it was considered that all instruments should be reviewed in the light of these principles.

Concern was expressed about the inaccuracy of some standard viscometers, in particular, orifice viscometers with diameter of orifice not much less than the length. Apart from difficulties of dribbling, lack of temperature control and lack of calibration against a master cup, the times of flow may have little or no relation to viscosity values. With some penetrometer results, it had frequently been assumed that it is possible to interpret them by the classical law of Stokes, assuming the behaviour was Newtonian; this was found not to be the case with greases, paints and thickened liquids.

In addition to visits to the Manchester Oil Refinery and to the engineering laboratories of the Metropolitan-Vickers Electrical Co., Ltd., an evening was devoted to an informal discussion opened by Dr. K. Weissenberg and Mr. S. M. Freeman (Shirley Institute, Manchester), who demonstrated some rheological phenomena that had come to light since the last conference. They dealt specially with anisotropy-time effects using elastic liquids and elastic solid/gas systems. The rheogoniometer was used to indicate relaxation in different directions.

E. W. J. MARDLES

FUNCTION OF THE LYMPHOCYTE

THE function of the lymphocytes in the mammalian body has long been the subject of conjecture. Now, at last, one definite function, and a very important one, has been ascribed to them, on impressive evidence. It appears that the lymphocytes synthesize and afterwards liberate into the blood the normal γ-globulin of the plasma and also the various antibodies which appear in the blood in immunity reactions. The antibodies are known to be simply specific modifications of γ-globulin. Furthermore, it has been shown that this liberation of γ-globulin by the lymphocytes, and in fact the whole activity of the lymphoid tissue, are controlled by one of the hormones of the adrenal cortex. At a conference on lymph held by the New York Academy of Sciences in April 1945, W. E. Ehrich (*Ann. New York Acad. Sci.*, **46**, 823; 1946) and A. White and T. F. Dougherty (*ibid.*, p. 859) presented the important contributions which they have made to this new knowledge of the lymphocyte.

It has long been known that about 200 million lymphocytes per hour enter the blood stream. They must, therefore, be removed from the blood at a corresponding rate, but where or how this occurs has been a mystery. It has now been shown that, as first suggested by Heiberg in 1922, a large proportion of the lymphocytes return to the germinal centres of the lymph nodes, where they undergo a process of 'dissolution'. It is not quite clear how the lymphocytes get back to the germinal centres, but it seems probable that they emigrate directly from the blood vessels which supply the lymphoid tissue, possibly from certain venules of peculiar structure which are to be found there. The process of dissolution involves the shedding of cytoplasmic fragments by a process of budding and also, in the case of many lymphocytes, complete cellular destruction, the nuclear remains being phagocytosed by the macrophages of the germinal centre. In the process of dissolution, γ-globulin, which is presumably synthesized by lymphocytes as a normal cytoplasmic component, is liberated and is carried away in the lymph stream to the blood.

The germinal centres are thus both the birthplace and graveyard of the lymphocytes, and their main function seems to be to manufacture and carry a store of γ-globulin which is liberated and made available to the body on their dissolution. γ-Globulin is thus one of the few plasma proteins, possibly the only one, not manufactured in the liver. The antibodies of the blood, which appear during the development of immunity to foreign proteins, bacteria and bacterial toxins, are known to be specific modifications of normal plasma γ-globulin, differing only in the configuration of the molecule and the arrangement of the constituent amino-acids. It is thought that, in an immunity reaction, the lymphocytes manufacture the specific antibody in place of the normal γ-globulin, and therefore liberate the antibody instead of γ-globulin when they disintegrate in the germinal centres.

Hitherto it had been supposed that the antibodies were manufactured by the cells of the reticulo-endothelial system. This theory, due to Metchnikoff, rested chiefly on the observation that reticulo-endothelial blockade reduced antibody formation. In order to reconcile this fact with the newer knowledge, Ehrich supposes that the antigen must first be ingested and partly digested by the reticulo-endothelial cells, the digestion products then stimulating the lymphocytes to form the specific antibody. It would seem unlikely, however, that antigen could be digested far, if at all, without losing its specific antigenic properties. White and Dougherty have shown that the hormone of the adrenal cortex stimulates the dissolution of lymphocytes in the germinal centres and so increases the liberation of γ-globulin and antibodies into the blood, and also, incidentally, reduces the total volume of lymphoid tissue in the body. A single injection of adrenal cortex hormone or of the adrenotrophic hormone of the pituitary gland causes a marked increase of lymphocyte destruction in the germinal centres, a lymphopænia and a rise in plasma globulin, the changes reaching a maximum about twelve hours after.

If an animal was first immunized to an antigen (sheep's red cells) and then some months later, when all the antibody had disappeared from the blood, injected with adrenal cortex hormone, the antibody reappeared in the blood in considerable amount. The therapeutic implications of this experiment are obvious and will no doubt be explored. It has also been shown that the total amount of lymphoid tissue present in the body is determined and controlled by the adrenal cortex, and the normal age involution of the lymphoid tissue (including the thymus) is ascribed to an increasing activity of the adrenal cortex, which is in turn due to an increasing activity of the anterior pituitary. The pituitary-adrenal mechanism for the release of γ-globulin and antibodies can be activated experimentally in a number of ways, for example, by hæmorrhage, heat, cold, X-rays, foreign proteins, injection of benzene or arsenite. From another point of view the lymphocytes of the body represent a considerable store of protein which can be rapidly released by the pituitary-adrenal mechanism in states of emergency.

Reports of a repetition of this work have not yet been published, and confirmation or otherwise of the somewhat surprising results will be awaited with interest. O. A. TROWELL

MINERAL PRODUCTION OF CANADA

"THE Canadian Mineral Industry in 1945", published by the Bureau of Mines, Ottawa (1946, pp. 103), contains reviews of the various metals, industrial minerals and fuels produced in the Dominion during 1945, and gives particulars in each case of sources of supply, uses, prices and tariffs, and figures for production, exports and imports. In order of value (stated in millions of dollars) the chief products are: aluminium (133·6); gold (103·8); coal (67·6); nickel (62); copper (59·3); zinc (33·3); platinum group (26·7); asbestos (22·8); lead (17·3); cement (14·2); petroleum (13·6); lime, limestone and marble (13·2); natural gas (12·3); sand and gravel (10·6); clay and clay products (8·3); silver (6); salt (4); peat (2); pyrite and sulphur (1·9); gypsum (1·8); silica (1·5); barite (1·3); magnesitic dolomite and brucite (1·3); granite (1·1); sodium sulphate (0·9); selenium (0·7) and cadmium (0·6). No corresponding figure for iron ore is given, but it is interesting to note that production, negligible only a few years ago, has recently increased enormously, and is expected soon to equal the requirements of the Canadian iron and steel plants. The Helen Mine, north of Lake Superior, and the Steep Rock Mine, west of Port Arthur, each produced more than half a million tons during 1945 and have very substantial reserves.

The temporary disappearance of magnesium from the above list is a symptom of war-time over-production, large stocks of the metal and its alloys having already been accumulated in Ontario. It may be a surprise to many to find aluminium at the head of the list. Although there is no bauxite in Canada, the Canadian aluminium industry is the second largest in the world, being exceeded only by that of the United States. The favouring factors are the low costs of hydro-electric power at points where the necessary raw materials can be cheaply assembled.

Canada's dominating position as a source of nickel is well known; it remains at about 80 per cent of the world total. Despite the drastic reduction in munitions manufactures, the many new uses found for nickel during the War, as in radar and extended utilization of nickel-bearing steels, are expected to provide an expanding market. Canada continued to be one of the leading exporters of copper, and to maintain its position—gained from the U.S.S.R. in 1934—as the leading producer of the platinum and palladium group of metals. Coal production is down a little and petroleum by as much as 15 per cent.

Production of oil from the Turner Valley field has been decreasing since 1942. The search for new fields in Alberta has so far been disappointing, but six producing wells have been completed in Saskatchewan, which appears as a small producer for the first time. The development of natural gas resources has been more successful, especially in Alberta. The new gas field recently discovered in Ontario beneath the floor of Lake Erie was brought into production by means of wells put down a mile from the shore.

ANALYTICAL GEOLOGY

THIS is the name given by A. B. Vistelius to the application of statistical analytical methods to numerical geological data and the subsequent interpretation of the results in the light of significant geological facts. In a series of five short articles*, he applies this method to the study of the porosity of rocks belonging to the oil-bearing strata of Permian age in the Transvolgian region of the U.S.S.R. The original data consist of a number of records of the coefficients of porosity (y) of rocks, taken in a number of bore-holes at a certain depth (x) below a definite stratigraphical horizon. Plotting the coefficient of porosity against depth, Vistelius obtains broken-line diagrams which are smoothed out so as to give continuous curves. It is then discovered that for all the bore-holes of the region these curves correspond to a definite formula, the equation of which is originally given as

$$y = m + nx + \exp\,(a_1x + b_1)\cos\,(\omega_1x - \varphi_1) + \exp\,(a_2x + b_2)\cos\,(\omega_2x - \varphi_2),$$

and then reduced to a general serial expression of the type

$$y' = \sum_{i=0}^{k} \exp\,(a_ix + b_i)\cos\,(\omega_ix + \varphi_i)$$

$$\text{where } k \leqslant 3.$$

Then the coefficients a_i, b_i, ω_i and φ_i are calculated for each bore-hole and the analogous coefficients for different bore-holes are compared and plotted on the geographical map by means of isopleths (contour lines corresponding to equal numerical values).

The isopleth maps, showing the regional distribution of the numerical values of the coefficients of the generalized formula, are then compared to other maps such as strato-isohyps maps or isopachyte (lines of equal thickness of a bed) maps of the region, and it is discovered that the isopleth maps of certain coefficients are analogous either to structural isohyps maps or isopachyte maps. This suggests that the distribution of porosity in a sedimentary complex obeys not only a certain periodic law, as expressed by the general formula, but is also linked up with the general geological structure of the region and is therefore related to the geological history of the sedimentary complex. The coefficient of periodicity (ω) appears to be especially significant, and the isopleth maps of this coefficient can be easily correlated with either the structural maps or the isopachyte maps. According to whether the members of the equation contain the minimum, maximum or intermediate value of ω, they are called micro-, macro- or meso-rhythms.

---

* Vistelius, A. B., *Compt. Rend.* (*Doklady*) *Acad. Sci. URSS.*, **44**, No. 1, 27 (1944); **49**, No. 1, 44 (1945); **49**, No. 7, 531 (1945); **54**, No. 6, 519 (1946); **55**, No. 3, 241 (1947) (Russian text).

To Vistelius all this suggests that porosity is closely related to the processes of deposition and epigenesis (cementation and leaching), and so can be used as a measure of what he calls the 'phase differentiation' of the sedimentary complex, the phases in this case being the solid phase (mineral components of rocks) and the liquid and gaseous phases (infilling the pore space). If the empirical equation of the vertical distribution of porosity is compared with the equation expressing the normal law of errors, or rather the function of distributed probabilities, one is able to get an estimate of the magnitude of the secondary processes (epigenesis) as compared with the magnitude of the primary processes (sedimentation). This is achieved by the construction of isopleth maps for kurtosis and skewness, which provide a sensitive method of discovering the distribution of 'fossilized processes'.

All this work is still in its pioneering stage and as presented can be appreciated only by geologists well versed in modern statistical methods. It is rather difficult to evaluate the significance of isopleth maps for equation coefficients when these are compared with structural contour maps (isohyps or isopachytes). In spite of this difficulty, this work appears very interesting and important. There is a suggestion that this method may have a wider applicability to geological problems in which the immediate data do not allow any direct correlation or deduction. The practical importance of the application of statistical methods to geology may be considerable. In the case discussed by Vistelius, the porosity of the rocks has a direct bearing on the distribution of reservoir beds in an oilfield, but it is not difficult to find many other instances of work of economic value in which statistical methods may have an application. Such are, for example, water supplies, distribution and grade of coal in coalfields, and other similar problems. S. I. TOMKEIEFF

ELEMENTARY PARTICLES AND THE GEOMAGNETIC FIELD

RECENTLY J. Barnóthy[1] has proposed an explanation of the elementary particles (protons, electrons, etc.) in terms of serial universes, each enclosed in one of higher order. The elementary particles of our universe are universes of a lower order; our universe is an elementary particle in a higher universe. The universes are three-dimensional curved ones enclosed in a four-dimensional space; that of an elementary particle has a two-dimensional intersection with our universe, which delimits a region excluded from the latter. Mass in an elementary universe becomes imaginary mass ($\sqrt{-1} \times$ mass) when viewed from ours; the gravitational attraction between two imaginary masses is a real electrostatic force. The spin of an elementary universe gives parts of its mass a velocity greater than c; this makes the imaginary mass acquire real linear and angular momentum. Nuclear forces in our universe are the counterparts of cosmical repulsions in the elementary universe. Protons and electrons arise from Einstein universes of negative and positive curvature; a neutron is formed by the combination of a proton and another particle arising from a de Sitter universe.

Barnóthy expresses these general ideas in a quantitative form. Like Eddington, by some of whose ideas he has been profoundly influenced, he derives an impressive list of theoretical values of fundamental constants, in good agreement with the experimental values. One must add that, again as with Eddington, it is often difficult to trace the interconnexions between different parts of his argument. In particular, the mechanism by which internal properties of a micro-universe react on our universe is far from clear.

Barnóthy claims to explain the proportionality between magnetic moment and angular momentum of sun and earth, to which Blackett and Babcock have recently directed attention. [Barnóthy's work was not suggested by that of Blackett and Babcock; a preliminary account of his ideas, dated September 13, 1946, was received by *Nature* last year, but was not regarded as sufficiently explicit to warrant publication. EDITORS.] He asserts that protons and neutrons possess, besides their real mass, an imaginary mass 643 times the electron-mass, and this imaginary mass behaves like an electric charge. The rotation of such a charge would produce terrestrial and solar magnetic fields of just the observed order of magnitude; but the suggestion is not at present satisfactory, since such a charge would produce a formidable electrostatic field, and Barnóthy declines to consider this field for the present. T. G. COWLING

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, December 15

ROYAL PHYSICAL SOCIETY OF EDINBURGH (at the Royal Scottish Geographical Society, Synod Hall, Castle Terrace, Edinburgh), at 5.15 p.m.—Symposium on "The Species Concept".

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY (in the Reynolds Hall, College of Technology, Manchester), at 5.30 p.m.—Prof. T. B. L. Webster: "Three Interpretations of Greek Vases" (Presidential Address).*

INSTITUTION OF THE RUBBER INDUSTRY, MANCHESTER AND DISTRICT SECTION (joint meeting with the SOCIETY OF CHEMICAL INDUSTRY, at the Engineers' Club, Albert Square, Manchester), at 6.15 p.m.—Dr. D. A. Harper: "The Technology of some New Condensation Rubbers".

ROYAL INSTITUTE OF CHEMISTRY, LONDON AND SOUTH-EASTERN COUNTIES SECTION (at Norwood Technical Institute, Knight's Hill, London, S.E.27), at 7 p.m.—Microchemical Exhibition and Demonstration (organised by Mr. J. T. Stock).

Tuesday, December 16

ROYAL SOCIETY OF ARTS, DOMINIONS AND COLONIES SECTION (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Mr. Colin Colahan: "Australian Art".

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 5 p.m.—Dr. F. Hepner: "Communications and History".

EUGENICS SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Dr. J. A. Fraser Roberts and Dr. Eliot Slater: "Genetics, Medicine and Practical Eugenics".*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Sir Charles Inglis, F.R.S.: "Mathematics in relation to Engineering, with Special Reference to a Recent Paper by the Lecturer on Shear Stress Determination".

SOCIETY OF CHEMICAL INDUSTRY, CHEMICAL ENGINEERING GROUP (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. J. G. Window: "Glass Equipment in the Chemical Engineering Industries".

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Annual General Meeting; at 6.15 p.m.—Scientific Papers.

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS GROUP (joint meeting with the LONDON SECTION of the INSTITUTION OF THE RUBBER INDUSTRY, in the York Room, Caxton Hall, Westminster, London, S.W.1), at 6.30 p.m.—Dr. D. V. N. Hardy: "Terylene and its Early Development".

TEXTILE INSTITUTE, MIDLANDS SECTION (joint meeting with the COVENTRY TEXTILE SOCIETY, at the Technical College, Coventry), at 6.45 p.m.—Mr. R. Meredith: "X-Rays in relation to Textiles".

SOCIETY OF DYERS AND COLOURISTS, SCOTTISH SECTION (at the Royal Technical College, Glasgow), at 7 p.m.—Dr. C. H. Giles: "Modern Methods of Colorimetric Analysis".

TEXTILE INSTITUTE, LANCASHIRE SECTION (at 16 St. Mary's Parsonage, Manchester), at 7 p.m.—Mr. L. L. Preston and Mrs. A. N. Thomas: "Radio Frequency Heating and Infra-Red Drying".

SOCIETY OF INSTRUMENT TECHNOLOGY, NORTH-WEST SECTION (at the College of Technology, Manchester), at 7.15 p.m.—Scientific Films (arranged by Mr. H. Ogden and Mr. F. Hill).

Wednesday, December 17

BRITISH SOCIETY FOR INTERNATIONAL BIBLIOGRAPHY (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2), at 2.30 p.m.—Papers.

CHEMICAL SOCIETY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 5 p.m.—Prof. John Read, F.R.S.: "Chemical Personalities a Century Ago".

ROYAL MICROSCOPICAL SOCIETY (in the Hastings Hall, B.M.A. House, Tavistock Square, London, W.C.1), at 5 p.m.—Films.

INSTITUTE OF PHYSICS, ELECTRONICS GROUP (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. R. Kompfner: "The Travelling-Wave Tube".

BRITISH RHEOLOGISTS' Club (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Papers on "War-time Rheological Investigations for the Services".

SOCIETY OF DYERS AND COLOURISTS, MIDLANDS SECTION (in Room 104, College of Technology, Leicester), at 7 p.m.—Mr. R. R. Clegg: "Textile Drying Technique".

INSTITUTION OF THE RUBBER INDUSTRY, SOUTHERN SECTION (joint meeting with the SOUTHERN SECTION of the PLASTICS INSTITUTE, at the Polygon Hotel, Southampton), at 7.15 p.m.—Mr. S. B. Turner: "Expanded Plastics".

SOCIETY FOR VISITING SCIENTISTS (at 5 Old Burlington Street, London, W.1), at 7.30 p.m.—Discussion on "Science and Fuel" (to be opened by Prof. D. M. Newitt, F.R.S., and Dr. Martin Ruhemann).

Thursday, December 18

INSTITUTION OF MINING AND METALLURGY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. F. H. Fitch: "The Tin Mines of Pahang Consolidated Co., Ltd.".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. G. K. Batchelor: "Progress and Difficulties in the Theory of Isotropic Turbulence".

PHYSICAL SOCIETY, LOW-TEMPERATURE GROUP (in the Lecture Theatre, Science Museum, Exhibition Road, London, S.W.7), at 4.30 p.m.—Second Annual General Meeting; at 5 p.m.—Discussion on "Insulating Materials and Methods for Use at Low Temperature" (to be opened by Prof. F. E. Simon).

ROYAL AERONAUTICAL SOCIETY (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6 p.m.—Prof. A. Thom and Mr. W. G. A. Perring: "The Work of the High Speed Tunnel".

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Discussion on "Infra-Red Spectra and Molecular Structure" (to be opened by Dr. H. W. Thompson, F.R.S.).

Friday, December 19

PHYSICAL SOCIETY (in the Lecture Theatre, Science Museum, Exhibition Road, London, S.W.7), at 5 p.m.—Sir Edward Appleton, F.R.S.: "Geomagnetism and the Ionosphere" (Fourth Charles Chree Address). (Fellows of the Royal Astronomical Society are invited.)

INSTITUTE OF INDUSTRIAL ADMINISTRATION, MANCHESTER CENTRE (in the Reynolds Hall, College of Technology, Manchester), at 7.15 p.m.—Sir Francis Joseph, Bart.: "Management and Recovery".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

BIOCHEMIST to St. James's Hospital—The Medical Officer of Health, Public Health Department (Hospitals Administration Section), 12 Market Buildings, Vicar Lane, Leeds 1 (December 20).

TECHNICAL ASSISTANT (preferably a woman) for Cod Liver Oil (Poultry) Standardization Laboratory, for work mainly connected with routine biological tests of vitamins and other substances—The Secretary, National Institute for Research in Dairying, Shinfield, Reading (December 20).

MACHINERY RESEARCH OFFICER for duties in connexion with the use and development of mechanical appliances in forestry—The Secretary, Forestry Commission, 25 Savile Row, London, W.1 (December 20).

LECTURERS IN (a) PHYSICS with subsidiary Mathematics, Ref. A.435/47A, (b) Electrical and Mechanical Engineering, Ref. D.378/47A, (c) Mechanical Engineering Drawing, Ref. C.733/47A, by the Ministry of Supply School of Electronics, Malvern—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (December 23).

PRINCIPAL RESEARCH OFFICER, and a SENIOR RESEARCH OFFICER, in the Research Unit of the Colonial Insecticides Committee at Porton, Salisbury—The Under-Secretary of State (Research Department), Colonial Office, Palace Chambers, Bridge Street, London, S.W.1 (December 29).

ASSISTANT ANALYST (male) in the County Chemical Laboratory, Stafford—The Clerk to the County Council, County Buildings, Stafford (December 29).

LECTURER IN MATHEMATICS—The Registrar, University College, Leicester (December 31).

ASSISTANT DIRECTOR—The Director, The University Observatory, Cambridge (December 31).

LECTURER IN CHEMISTRY—The Secretary, Edinburgh and East of Scotland College of Agriculture, 13 George Square, Edinburgh (December 31).

SENIOR LECTURER (or LECTURER) IN PHYSICS in Natal University College, Pietermaritzburg—The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (December 31).

LECTURER IN AGRICULTURAL ENGINEERING in Canterbury Agricultural College, New Zealand—The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (December 31).

SENIOR RESEARCH OFFICER or RESEARCH OFFICER IN THE DIVISION OF FOOD PRESERVATION AND TRANSPORT, Homebush, N.S.W.—The Secretary, Australian Scientific Research Liaison Office, Australia House, Strand, London, W.C.2, quoting No. 1467 (January 3).

SENIOR RESEARCH OFFICER IN THE DIVISION OF AERONAUTICS, Melbourne—The Secretary, Australian Scientific Research Liaison Office, Australia House, Strand, London, W.C.2, quoting No. 1478 (January 3).

LECTURER (with qualifications in electronics) IN THE FLUID MOTION LABORATORY—The Registrar, The University, Manchester 13 (January 31).

I.C.I. RESEARCH FELLOWSHIPS IN BIOCHEMISTRY, CHEMISTRY, ENGINEERING, PHARMACOLOGY or PHYSICS—The Secretary of University Court, The University, Glasgow (March 31).

I.C.I. RESEARCH FELLOWSHIPS IN BIOCHEMISTRY, CHEMISTRY, CHEMOTHERAPY, ENGINEERING, METALLURGY, PHARMACOLOGY, PHYSICS and allied subjects—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 30).

TURNER AND NEWALL RESEARCH FELLOWSHIPS IN ENGINEERING, INORGANIC CHEMISTRY or PHYSICS, or any allied science—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 30).

SOIL LABORATORY ASSISTANT by the Government of Northern Rhodesia for the Public Works Department—The Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M.N.18396.

RESEARCH ASSISTANT IN BIOCHEMISTRY—Prof. E. J. King, Postgraduate Medical School of London, Ducane Road, London, W.12.

LECTURER IN MATHEMATICS—The Director of Education, The Polytechnic, 309 Regent Street, London, W.1.

TECHNICIAN (Grade B) for research laboratory of biochemistry and physiology in relation to mental disorder—The Physician Superintendent, Runwell Hospital, Wickford, Essex.

LABORATORY TECHNICIAN for physiological laboratory in the Department of Zoology—The Secretary, University Museum, Oxford.

SENIOR LABORATORY STEWARD IN THE PHYSICS DEPARTMENT—The Secretary, Northampton Polytechnic, St. John Street, London, E.C.1.

LECTURER IN PHYSICS—The Clerk, Northern Polytechnic, Holloway, London, N.7.

PHYSICIST, PHYSICAL CHEMISTS (2), an ORGANIC CHEMIST, and a TEXTILE TECHNOLOGIST—The Acting Secretary, British Rayon Research Association, Bridgewater House, 58 Whitworth Street, Manchester 1.

TECHNICAL INDEXER (woman) in the PLANT AND ANIMAL PRODUCTS DEPARTMENT—The Establishment Officer, Imperial Institute, South Kensington, London, S.W.7.

LABORATORY TECHNICIAN (Grade C) IN THE PHYSICS DEPARTMENT—The Warden and Secretary, Royal Free Hospital School of Medicine, 8 Hunter Street, London, W.C.1.

PHYSICISTS OR PHYSICAL CHEMISTS, and TECHNICAL ASSISTANTS with some experience, preferably, in the clay industries—The Director of Research, British Refractories Research Association, Mellor Laboratories, Hanley, Stoke-on-Trent.

SCIENTIFIC RESEARCH AND PUBLIC EXPENDITURE

THE statistical survey of scientific and technical research in British industry recently made by the Industrial Research Secretariat of the Federation of British Industries, while admittedly incomplete, is a valuable supplement to the survey of expenditure on research and development which formed the subject of the Third Report of the Select Committee on Estimates for the Session 1946–47 (132–1. London : H.M. Stationery Office, 1947. 6*s.* net). The Federation's report is based on the 471 replies received to about nine hundred copies of a questionnaire circulated to industrial firms known or thought likely to be carrying out research. It is estimated that the survey covers some seventy-five per cent of the industrial research effort of Great Britain, although probably not more than fifty per cent of the firms carrying out research. On this assumption the total annual expenditure by industry on research and development within its own establishments is of the order of thirty million pounds, which represents about two thirds of one per cent of the total annual value of British manufacture.

This figure may be compared with that of £5,442,000 obtained from an earlier survey by the Federation and based on returns from 566 firms in 1938 ; but it is more pertinent to set it against the national estimated expenditure of £69 millions analysed in the report of the Select Committee on Estimates. The estimate for the Department of Scientific and Industrial Research for 1947–48 amounts to £3,118,289, or about ten per cent of the expenditure by industry itself ; but in addition it is estimated that other Departments are expending £1,500,500 on industrial research. The vote for Post Office research amounts to £750,000, for agricultural and fisheries research to £2,150,925, for medical research to £710,850, for research in the Dominions and Colonies to £538,825. In addition to miscellaneous grants for scientific investigation amounting to £70,560, account should also be taken of the expenditure by the universities on scientific research. This is of fundamental importance to the State as well as to industry, but it is difficult to obtain even an approximate idea of its magnitude. Expenditure on teaching cannot, of course, easily be separated from that on research, and the Select Committee estimates that of the present vote of £11,875,000 in aid of the universities, something less than £3,500,000 is for science, technology and agriculture. Part of the expenditure of just over £2 millions on medical and dental education will be for research, and there are also capital grants of probably not less than £1,800,000 ; but it would be rash to put the nation's expenditure on fundamental research as reaching anywhere near £5 millions, at least on these figures.

What overshadows all these sums, however, is the expenditure of £60,351,000 on research and development for the Admiralty and the Ministry of Supply, which is more than double the total estimated research expenditure of the whole of British industry. The Select Committee refrains from detailed comment as it proposes to deal with the problem of expenditure on defence research in a later report; but there is a *prima facie* reason for questioning whether the present distribution of expenditure on research and development is that most to be desired in the light of civil and military needs and national resources at the present time. The diversion of at least a third of this effort from defence purposes to civil research has been urged by the Association of Scientific Workers; but without the detailed returns supplied to the Select Committee, which it was considered undesirable to publish, it is not easy to judge whether a diversion of such magnitude would be desirable.

What is imperative is that the nation's expenditure on fundamental research, upon which defence no less than industrial development alike depend, should be used to the best advantage. There can be little doubt that our first concern should be, as Sir Henry Dale urged at Dundee, to promote the extension of fundamental knowledge, and build up again our scientific capital on which the needs of war have drawn so heavily. It is vital that our academic leaders of research, men with ideas and inspiration, should lack neither disciples, assistants, nor equipment. In urging this, Sir Henry Dale was thinking largely of the diversion of scientific minds from creative research to administrative work; and the present shortage of scientific man-power makes it important that due regard should be had to this danger, all the more because our war experience has demonstrated that the field in which the scientific worker can usefully operate extends far beyond that of the laboratory where he normally pursues his business.

That point was well made by Sir Edward Appleton in his A. D. Little Memorial Lecture* at the Massachusetts Institute of Technology in November 1946, when he indicated that, as emphasized in the Barlow Report, the Government order of priorities is now: universities and fundamental research; civil research (Government and industrial); and defence research. What needs to be remembered first, however, in this connexion, is that the limitations on expansion of fundamental research are not primarily financial but those of man-power. It was made clear in the evidence received by the Select Committee on Estimates that lack of money is not the difficulty holding up the pursuit of profitable new lines of research at the present time: the principal needs are for men and accommodation.

These two needs are closely linked, and both are bound to be affected by the Government's policy of priorities and of the restriction of capital expenditure due to the economic crisis. The Select Committee emphasizes that, while it may be open to question whether the allotment to pure research and to scientific teaching is adequate to secure the twin objects of gaining natural knowledge, which provides the foundation for the whole structure of applied science, and of providing the required output of trained research workers, the evidence suggests that the allocation for the current year is probably as much as can be usefully and economically absorbed. This problem is raised, and also the further question whether the expenditure on defence research represents an equitable distribution between civil and military needs; and on the adequacy of the rough estimate of 21 per cent of national expenditure on research for industrial research, no comment is made.

On that point an appended memorandum from the Department of Scientific and Industrial Research gives a little further information. Of the present vote, £942,000 represents grants to research associations, a figure which it is estimated will reach £1·million when the expenditure of the Department reaches its full post-war level of £4,035,000. Of the firms replying to the questionnaire from the Federation of British Industries and expending more than £1,000 per annum on research, ninety per cent possess their own separate research laboratory or department and thirty per cent carry out research in their own production department; while available estimates indicate that half the firms contemplate a twenty-five per cent increase of qualified research staff by the end of 1947 and a comparable further increase between 1948 and 1950.

These figures alone attest the importance of precise surveys of man-power requirements in relation to the expansion of the universities and colleges of technology, as was indicated recently in these columns (see *Nature*, November 29, p. 742). The memorandum from the Department of Scientific and Industrial Research, however, directs attention to the third factor in the situation, on which the Select Committee also comments. The Department of Scientific and Industrial Research, in addition to its primary responsibility for promoting and organising scientific work with a special view to its application to trade and industry, has also a duty to carry out scientific research within its scope required by other Departments of State. The memorandum indicates the provision being made for the discussion of common problems necessary for the most effective co-ordination; one responsibility of the new central intelligence group of the Department will be to make themselves generally familiar with what is going on in university and Government research organisations and, so far as possible, with the needs of industry, and then to effect such cross-fertilization as they can.

On the industrial side, the Federation of British Industries, through its Industrial Research Secretariat, is already doing much to promote the general exchange of scientific and technical information, and the inquiry indicated that most firms are satisfied with present arrangements. The Select Committee on Estimates, commenting on the dangers of overlapping and waste of effort in the present administrative organisation, emphasizes the value and need of a first-class system of liaison at all levels and the greatest possible interchange of information not only on results, but also on projects. It was satisfied that, in general, improvements in the existing organisation are being made as weak spots are revealed, and since these matters are under consideration by the Defence Research Policy Committee and the Advisory Council on Scientific Policy, it makes no further comment.

---

* Science, Government and Industry. By Sir Edward V. Appleton. (Inaugural of the Arthur Dehon Little Memorial Lectures at the Massachusetts Institute of Technology, at Cambridge, Massachusetts, November 19, 1946.) Pp. 38. (Cambridge, Mass.: Massachusetts Institute of Technology, 1946.)

The Select Committee agrees with the opinion, which Sir Edward Appleton expressed at the British Commonwealth Scientific Conference last year, that it is far too early to decide what the ideal Government organisation for research should be, and the machinery for fostering scientific effort must remain for many years in a state of active development. That, however, does not exclude the need for closer study of the whole question of the organisation of scientific and industrial research in Great Britain, and indeed is a reason for further trial and experiment with the forms of institution best likely to achieve our purposes. There is general agreement, both in Great Britain and in the United States, that fundamental research is seldom a proper field for Government expenditure and that Government assistance is best given indirectly, through block grants to universities, research institutes and even individuals; but even here there may be room for inquiry as to whether there is in Britain a sufficiency of research institutions of the range and type to ensure that all branches of science are adequately covered. While the urgency of the present need for more and more production makes it essential to drive existing institutions to the utmost, the general unrest following a great war nevertheless provides both the right atmosphere for experiment with new ways of approach and the incentive to extract from each everything that can be of value for the future.

SYNTHETIC RUBBER

Butalastic Polymers

Their Preparation and Applications; a Treatise on Synthetic Rubbers. By Frederick Marchionna. Pp. vii+642. (New York: Reinhold Publishing Corporation, 1946.) 8.50 dollars.

THE development of synthetic rubber is one of the outstanding achievements of chemical industry in recent years. The chronicler of the story of this achievement is, however, faced with a multiplicity of difficulties. A comprehensive account must include, first the manufacture of the monomer, second the polymerization of the monomer, and third the fabrication and properties of a wide variety of articles made from rubber. The first part is a matter of large-scale industrial catalytic chemistry where the essential techniques are already well established in other fields of chemical engineering. The second is based on scientific principles, but is also compounded of much empiricism because there has not been time to go into these principles in an adequate manner so that the mechanism of polymerization is fully understood. The third is rubber technology applied to materials which have usually turned out to be rather more difficult to work with than natural rubber. Further, developments have mainly occurred in the United States, Germany and the U.S.S.R., and there has naturally been no interchange of information between these countries. Even if there had not been a world war, it is extremely doubtful whether the operators in these respective countries would have divulged the 'know how' regarding these processes so that an author could write a critical summary of the present-day position.

Dr. Marchionna has therefore had to face very considerable difficulties in writing an up-to-date account of the subject. The book was written before much information became available through the Allied teams of investigators sent to Germany and before the vast amount of work done for the rubber research programme in the United States began to appear in the scientific literature. There was thus only available to the author a considerable volume of earlier published work on the attempts made to synthesize rubber-like materials and a host of patents relating to the possible processes for the manufacture of monomer, for the polymerization of monomers and for the working up of the rubbers so produced; but of course with little guidance as to their real worth or economic practicability. In view of this awkward state of affairs, it is impossible to prepare a critical account of the various phases of the subject or even to give a personal opinion of the relative merits of competing processes or the various types of rubber now commercially available.

The contents of the book are restricted to what the author conveniently terms butalastic polymers, that is to say, synthetic elastomers in which the repeating unit was originally a diene. The volume is divided into three parts. The first deals with laboratory and technical methods of making isoprene, dimethyl butadiene, butadiene and halogen derivatives of dienes. Although butadiene is now regarded as the most important diene, the space devoted to it is perhaps a little disproportionately small. Part 2 is devoted to the problems involved in polymerization. Here the emphasis is mainly on the methods found empirically for diene polymerization, and there is no general account of polymerization from the kinetic point of view. Again this is reasonable, because diene polymerization has not yet yielded to accurate kinetic methods in view of the many complications that arise, especially in emulsion or sodium polymerization. Unfortunately, the lack of published information has precluded a detailed description of the processes currently used in the United States. Part 3 describes the technology of synthetic rubber, dealing with the coagulation of the emulsion and the incorporation of the usual rubber-compounding agents. Then there are sections dealing with all the usual applications of rubber in industry, special note being paid to the properties of synthetic as contrasted with natural rubber. There are comprehensive indexes to the book, which is well produced and excellently printed.

This, then, is the first comprehensive attempt to give a balanced and connected account of an industry which started many years ago, developed very slowly indeed and did not really come into its own until war compelled a tremendous amount of scientific and technological effort to be brought to bear in order to make certain that synthetic rubber would, in fact, be a practical proposition. Dr. Marchionna has attained success in a very difficult task. Any shortcomings which the book possesses are in the main due to the information not being available. It is to be hoped that when a second edition is required the war-time experiences will be incorporated, so that the reader can then discover what indeed are the scientifically and economically satisfactory ways of making and manipulating synthetic rubber.

H. W. MELVILLE

BIOLOGICAL SIGNIFICANCE OF NUCLEIC ACID

Nucleic Acid

(Society for Experimental Biology Symposia No. 1: Published for the Company of Biologists on behalf of the Society for Experimental Biology.) Pp. vii+290+18 plates. (Cambridge: At the University Press, 1947.) 35*s.* net.

IN 1914 Walter Jones began the preface to his monograph on nucleic acids with the words, "The nucleic acids constitute what is possibly the best understood field of Physiological Chemistry . . ." That was then a tenable point of view; but twenty years later it would have been absurd. There are fashions in everything, including biochemistry, and nucleic acids went largely out of fashion or were swamped by the growth of our knowledge of proteins, oxidation mechanisms and the other processes that characterized the development of biochemistry in the 1930's. The boom–slump–boom cycle is, however, not confined to economics, and a nucleic acid boom is now upon us. Much new knowledge of the intrinsic properties and biological behaviour of the nucleic acids has been gained during the past few years; but there seems to have been a disproportionate flood of review articles, conferences and symposia. Stocktaking is valuable, but what is now needed in cytochemistry is more stock rather than more surveying.

The present volume gives the text of nineteen papers delivered at a symposium in Cambridge in 1946. The first articles deal with the chemical and physico-chemical properties of nucleic acids and nucleotides, and in them emphasis is placed on the large body of pure assumption that has in the past done duty for knowledge in the field. The late Prof. J. Masson Gulland and his colleagues survey the structural evidence that can be derived from degradation experiments, and point out that the abandonment of the tetranucleotide structure greatly increases the theoretical possibilities of isomerism among the nucleic acids. Evidence on structure is also given in Lythgoe and Todd's brief but lucid description of their extensive series of nucleotide syntheses. Kalckar describes new techniques for the microanalysis of purines by ultra-violet absorption, and gives some of the metabolic conclusions gained with them.

A thoughtful critique of the validity of many cytochemical methods, by Danielli, makes a good introduction to the more biological part of the symposium. Brachet and Caspersson present much evidence that regions or times of intense protein synthesis are correlated with a high nucleic acid content. Although each individual piece of evidence is not by itself wholly convincing, the accumulated mass is most impressive. Two other articles stand in interesting contrast. With pleasing exuberance, Darlington speaks of "nucleic acid as the molecular midwife of all reproductive particles" but, while re-writing cytology, gives no hint, in this article, of the technique and observations on which his conclusions are based. Stedman proceeds more cautiously and continues his valuable attempt to convince cytologists and geneticists that there is more in the nucleus than protamine or histone and nucleic acid. There is perhaps a danger that a new dogma may be built up if the unfractionated protein that can be extracted from all the nuclei that have been studied is called 'chromosomin'. That other proteins are present is obvious; that these proteins are sufficiently uniform in chemical type to deserve a name is arguable.

The printing and format of the book, which appears to be the first of a new series, are good; but it is a pity that the titles of papers have been put at the head of both left- and right-hand pages. It would have been helpful to have the author's name on one side. It is also a pity that such a high price had to be charged for a work which, although useful, is essentially ephemeral.

N. W. PIRIE

NOAH'S NIGHTMARE

Built Before the Flood

The Problem of the Tiahuanaco Ruins. By H. S. Bellamy. Revised and enlarged edition. Pp. 192. (London: Faber and Faber, Ltd., 1947.) 21*s.* net.

TIAHUANACO is an important site in South American archæology, and although it is not the only one, it has something about it which, like Glastonbury, stimulates the imagination of the uncritical, who tend to exalt it above all others. Here are some facts which must be borne in mind in considering it in relation to the subject as a whole. Not only its famous stone ruins but also its pottery belong to a very characteristic and easily recognized style. Their distribution in the Andes is restricted to the neighbourhood of Tiahuanaco itself, but on the coast a closely related style in pottery and textiles, little later than the culmination of the style in the Andes, is widespread. This is later than the well-known Mochica culture of the north coast, now dated with some certainty at *c.* A.D. 1000. When due allowance has been made for the time taken for Tiahuanaco influence to spread from the Andes to the coast, this shows that some time late in the first millennium is a reasonable estimate for its date. In the central and south parts of the coast, pre-Tiahuanaco cultures, earlier than the Mochica but still datable within the first millennium A.D., have yielded abundance of perfectly preserved textiles and other fragile and perishable materials in shallow graves, owing their very existence to continuous drought since they were buried. In the extreme north of Chile, it has been proved that the relation between land and sea cannot have altered more than about 15 metres at the outside (in the sense of a rise of land) since the arrival of pre-pottery man, long before any sign of Tiahuanaco influence.

The contention of this book is, briefly, that Tiahuanaco was built "certainly not less than a quarter of a million years ago", when a satellite preceding the moon dominated the heavens, and that it was overwhelmed by a great "girdle tide" which this satellite raised in the equatorial regions shortly before its disintegration. These ideas are based on the speculations of an Austrian named Hoerbiger, and it is claimed that the carvings on the monolithic gateway at Tiahuanaco constitute a calendar which fits in with his scheme. That we are not told how the older fragile remains on the coast survived an inundation of some 14,000 ft. of water and other catastrophic happenings is a consequence of the failure to consider a site in its context, which is frequent in this sort of writing.

The age ascribed to the ruins makes them contemporary with part of the European palæolithic period, when it is most unlikely that man, even at that lowly stage of development, had reached any part of the American Continent. On the other hand, the idea that a satellite approached the earth and disintegrated, and that the moon was 'captured', all in Pleistocene times, is unlikely to commend itself to men of science. In view of the startling contradiction between Mr. Bellamy's conjectures and the geological time-scale, it is lost labour to follow him through the tortuous paths of his interpretation of the carvings on the Tiahuanaco gateway. This has given rise to divers interpretations—it has even been claimed that it has something to do with the Old Testament—but there is no reason whatever why it should have been a calendar.

This book first appeared in 1943, and it was reprinted in 1944. That there should now be a "new revised and augmented edition", little altered except for a six-month shift in certain signs and the addition of twenty-seven pages of astronomical explanation by another author, provokes the suggestion that its vogue may be due to the hardness of the times which drives men to seek escape in fantasy.

G. H. S. BUSHNELL

EVOLUTION ON GALAPAGOS

Darwin's Finches

By David Lack. Pp. x + 208 + 9 plates. (Cambridge: At the University Press, 1947.) 21*s*. net.

THE theories of Darwin, and particularly those propounded in the "Origin of Species", are subjects of evergreen interest both to laymen and to biologists, and it is constantly worth while to examine and re-examine them in the light of the newest knowledge. To-day it can be said that they have stood the test of years of antagonistic criticism and of more than a generation of precise biological research, and have re-emerged so triumphantly that Prof. R. A. Fisher has recently spoken of a renaissance of Darwinism. It is therefore of special interest to read Mr. Lack's account of the latest expedition to what is perhaps the most important region visited by Darwin, the Galapagos Islands, and to learn more of the peculiar fauna of that place. What Darwin himself once said is still true: "The natural history of these islands is eminently curious, and well deserves attention".

The Islands are oceanic, and their colonization by land animals appears to have been haphazard and of rare occurrence. To-day the main ecological niches are fully occupied, but by most unusual species. The present account concerns in particular the four genera and fourteen species of birds which have become known as Darwin's finches. It is presumed that they have all evolved from a common stock, a small group of immigrants from the American mainland, and that some of them, experiencing no competition but their own from that time onwards, have undergone unique modifications of structure and habit. Some of them, the ground finches, retained the seed-eating habit, but others, the tree finches, became insectivorous. Of the whole series, the most extraordinary are the woodpecker finch and the warbler finch. Had the niches now occupied by these two birds been already filled by a true woodpecker and a true warbler, it is suggested that such development could never have taken place.

The first lesson which the Islands teach is the great variety which can develop in a small virgin country from a severely restricted beginning, a lesson which is repeated there by many other animals and by the plants. A second is the paramount importance of geographical isolation for species formation. Not only has it been necessary that the colonists should be cut off from their parent stock, but the theory is also advanced that each of the various finch species must have arisen in the isolation of one or other of the Islands and later extended its range. To-day, where they meet, the species persist only because they have come to occupy different ecological niches, and this in turn must have tended to increase their specialization. In contrast, the only one of Darwin's finches which is present on Cocos Island has remained a single species. The situation of Cocos ensures almost complete isolation from the mainland, but being a single small island it offers no chances of isolation within its borders.

Mr. Lack's restatement and development of the problem of Darwin's finches is admirably done. The material summarized, the reviews which are given of past and present theories, as well as the individual views expressed by the author, are all highly stimulating and valuable, and there is an extensive bibliography. The style is pleasant, the printing is excellent, and although the photographs are not up to present-day standards, the illustrations are adequate. It is a book which will be of great interest to all those, amateur and professional, who are intrigued by the problems of the origin of species.

W. S. BULLOUGH

INTRODUCTORY BIOLOGY

Biology for Medical Students

By C. C. Hentschel and Dr. W. R. Ivimey Cook. Pp. xii+752. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1947.) 25*s*. net.

IN the fourth edition of this widely used text-book the authors have taken the opportunity of considerable revisions of both the text and the illustrations. This applies particularly, so far as the text is concerned, to the botanical part; fewer changes and additions have been made in the zoological section, though there, too, the alterations are extensive.

The botanical part of this text-book has now grown to a well-rounded introduction to botany, which in scope might indeed be of use to a first-year science student; plant physiology has been extensively treated, and it was the aim of the authors to lay in this way the foundations for a later study of human physiology. The zoological part covers fully the requirements of the first-year medical student.

Criticism concerns chiefly the illustrations. Though a great number of the photographs are excellent, the quality of the diagrams varies considerably. Illustrations of the same organ in the three vertebrate types under discussion (for example, the inner ear, Figs. 255, 277 and 305, or the heart, Figs. 240, 267, 293 and 294) are not comparable and make a comparative appreciation by the student very difficult. Some of the drawings (for example, Fig. 268 or Fig. 300) are reduced too much and the many labelled details can only cause confusion; and the student will find some drawings of the chick's embryology very difficult to understand.

But in spite of these blemishes the new edition will continue to be a useful guide to the medical student in his first-year work.

A. S.

Theory of Lie Groups, I

By Claude Chevalley. (Princeton Mathematical Series.) Pp. xii + 217. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1946.) 20*s.* net.

IN recent years great advances have been made in our knowledge of the fundamental structures of analysis, particularly of algebra and topology, and an exposition of Lie groups from the modern point of view is timely. This is given admirably in the book under review, which could well have been called "Lie Groups in the Large". To make such a treatment intelligible it is necessary to re-examine from the new point of view such subjects as the classical linear groups, topological groups and their underlying topological spaces, and analytic manifolds. Excellent accounts of these, with the study of integral manifolds and their constructions in the large, are given in the earlier chapters. In Chapter 4 we come to the definition of an analytic group and its underlying manifold, and to the introduction of the important concept of a Lie algebra associated with an analytic group. A Lie group is then defined as a locally connected topological group related in a certain way to some analytic group; from this it follows that the concept of Lie algebra can be used freely when dealing with Lie groups. Chapter 5 contains an account of Cartan's calculus of exterior differential forms and its application to the theory of Lie groups. The final chapter is concerned with compact Lie groups, and after a brief consideration of the general theory of representations it is proved, among other things, that every representation of a compact Lie group is semi-simple.

The style of writing, though very condensed, is clear, and the printing is excellent. The notation is that of the modern school, with 'union' ($\cup$) and 'intersection' ($\cap$) in place of the older 'sum' and 'product' of sets. (A misprint has unfortunately interchanged the symbols $\cup$ and $\cap$ in their definition on p. xii.) The author promises a second volume, to be mainly concerned with semi-simple Lie groups.

A. G. WALKER

Animal Nutrition

By Prof. Leonard A. Maynard. (McGraw-Hill Publications in the Agricultural Sciences.) Second edition. Pp. xviii + 494. (New York and London: McGraw-Hill Book Co., Inc., 1947.) 25*s.*

THIS is one of the very few books which deal adequately with the fundamentals of the biochemistry and physiology of nutrition and with the applications of this knowledge to the feeding of farm animals. Since the first edition was published some nine years ago, much of the newer knowledge of nutrition has emerged, and this has meant extensive alterations in the sections on amino-acid, vitamin and mineral nutrition. In his preface, the author points out that owing to the limited opportunity which was enforced by war and its aftermath, it has been impossible to take account of the results of recent research in foreign countries, because the data have either remained unpublished or the journals containing them have not reached his desk. The student is warned by the author that he should not thereby gain a distorted picture of the progress of our knowledge of this very important field of physiology and chemistry. The present volume takes us up to the end of March 1946.

It is difficult to single out any particular parts for special comment, but the chapter on mineral deficiency is especially well treated, and the chapters on feeding experiments contain one of the best reasoned discussions on the pros and cons of the paired-feeding technique. In the author's view this method would appear to find its largest usefulness in comparisons in which food consumption is not markedly restricted by the conditions imposed, and in which the measure is in terms of the specific effect of the nutrient under study, instead of the more general measure of increase in weight. It is considered that there are many problems concerning which the use of separate experiments of both *ad libitum* and controlled feeding will give much more information than either procedure alone.

The chapters on growth, reproduction, lactation and work production are likewise excellent. In its clarity and brevity this work has few equals.

D. P. CUTHBERTSON

Photoelectric Cells

By Dr. A. Sommer. (Methuen's Monographs on Physical Subjects.) Pp. viii + 104. (London: Methuen and Co., Ltd., 1946.) 5*s.* net.

DR. SOMMER is well known for his work on photo-electric cells, and in this monograph he collects the basic work done by himself and others between 1931 and 1945. While there have been excellent texts on the industrial applications of photo-electric devices, there appears to be no review of the theoretical and research work since about 1934, so we are grateful to Dr. Sommer for his work and his bibliography. He is here concerned solely with photo-emissive cells. Commencing with Hertz, Planck and Einstein, he outlines the theory of emission, and shows how the number of materials useful as photo-emitters is strictly limited by ionization energy and work function, as well as physical properties. He then deals with the relationship of the wave-length of the incident light, the resulting emission, and the effect of gas in the enclosure. The manufacture of photo-cathodes is then outlined, and also the way in which they can be used for practical applications. Of great value is his critical table outlining the suitable types of cells for established technology, such as photometry, sound-film reproduction, picture-telegraphy, and television.

L. E. C. HUGHES

City Region and Regionalism

A Geographical Contribution to Human Ecology. By Robert E. Dickinson. (International Library of Sociology and Social Reconstruction.) Pp. xv + 327. (London: Kegan Paul and Co., Ltd., 1947.) 21*s.* net.

WHILE this book is not directly about planning, it deals with matters and conceptions that are essential to any far-sighted planning schemes. Human ecology, as the relation of society to the area in which it lives, is a difficult but most important study and one that is too often overlooked in schemes of administration. The spatial relations of human society is a study that has received too little attention in Great Britain. The city is a regional centre of a larger or smaller area, and its function as such is an important condition in delimiting regions within any country. Some cities weld together larger areas than others and size is not a necessary criterion of this function. Mr. Dickinson deals mainly with the town or city as a regional capital, but has also a good deal to say on the possible delimitation of regions in the United States, France and England and Wales. The book merits close attention.

EVIDENCE FOR THE EXISTENCE OF NEW UNSTABLE ELEMENTARY PARTICLES

By Dr. G. D. ROCHESTER
AND
Dr. C. C. BUTLER
Physical Laboratories, University, Manchester

AMONG some fifty counter-controlled cloud-chamber photographs of penetrating showers which we have obtained during the past year as part of an investigation of the nature of penetrating particles occurring in cosmic ray showers under lead, there are two photographs containing forked tracks of a very striking character. These photographs have been selected from five thousand photographs taken in an effective time of operation of 1,500 hours. On the basis of the analysis given below we believe that one of the forked tracks, shown in Fig. 1 (tracks *a* and *b*), represents the spontaneous transformation in the gas of the chamber of a new type of uncharged elementary particle into lighter charged particles, and that the other, shown in Fig. 2 (tracks *a* and *b*), represents similarly the transformation of a new type of charged particle into two light particles, one of which is charged and the other uncharged.

The experimental data for the two forks are given in Table 1; H is the value of the magnetic field, α the angle between the tracks, p and Δp the measured momentum and the estimated error. The signs of the particles are given in the last column of the table, a plus sign indicating that the particle is positive if moving down in the chamber. Careful re-projection of the stereoscopic photographs has shown that each pair of tracks is copunctal. Moreover, both tracks occur in the middle of the chamber in a region of uniform illumination, the presence of background fog surrounding the tracks indicating good condensation conditions.

Though the two forks differ in many important respects, they have at least two essential features in common: first, each consists of a two-pronged fork with the apex in the gas; and secondly, in neither case is there any sign of a track due to a third ionizing particle. Further, very few events at all similar to these forks have been observed in the 3-cm. lead plate, whereas if the forks were due to any type of collision process one would have expected several hundred times as many as in the gas. This argument indicates, therefore, that the tracks cannot be due to a collision process but must be due to some type of spontaneous process for which the probability depends on the distance travelled and not on the amount of matter traversed.

TABLE 1. EXPERIMENTAL DATA

Photograph	H (gauss)	α (deg.)	Track	p (eV./c.)	Δp (eV./c.)	Sign
1	3500	66·6	*a*	$3 \cdot 4 \times 10^8$	$1 \cdot 0 \times 10^8$	+
			b	$3 \cdot 5 \times 10^8$	$1 \cdot 5 \times 10^8$	−
2	7200	161·1	*a*	$6 \cdot 0 \times 10^8$	$3 \cdot 0 \times 10^8$	+
			b	$7 \cdot 7 \times 10^8$	$1 \cdot 0 \times 10^8$	+

This conclusion can be supported by detailed arguments. For example, if either forked track were due to the deflexion of a charged particle by collision with a nucleus, the transfer of momentum would be so large as to produce an easily visible recoil track. Then, again, the attempt to account for Fig. 2 by a collision process meets with the difficulty that the incident particle is deflected through 19° in a single collision in the gas and only 2·4° in traversing 3 cm. of lead—a most unlikely event. One specific collision process, that of electron pair production by a high-energy photon in the field of the nucleus, can be excluded on two grounds: the observed angle between the tracks would only be a fraction of a degree, for example, 0·1° for Fig. 1, and a large amount of electronic component should have accompanied the photon, as in each case a lead plate is close above the fork.

We conclude, therefore, that the two forked tracks do not represent collision processes, but do represent spontaneous transformations. They represent a type of process with which we are already familiar in the decay of the meson into an electron and an assumed neutrino, and the presumed decay of the heavy meson recently discovered by Lattes, Occhialini and Powell[1].

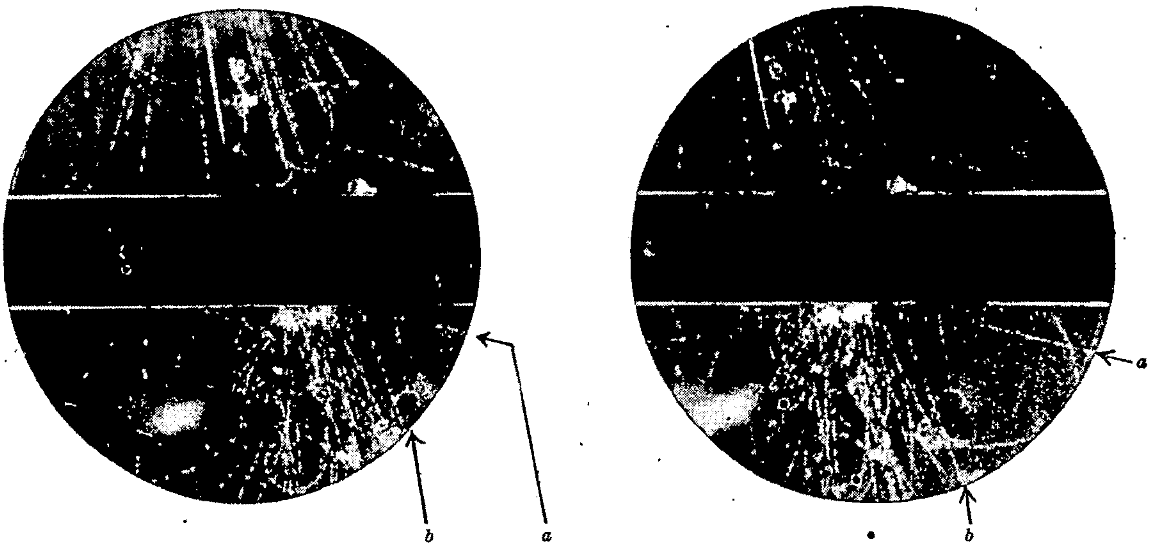

Fig. 1. STEREOSCOPIC PHOTOGRAPHS SHOWING AN UNUSUAL FORK (*a b*) IN THE GAS. THE DIRECTION OF THE MAGNETIC FIELD IS SUCH THAT A POSITIVE PARTICLE COMING DOWNWARDS IS DEVIATED IN AN ANTICLOCKWISE DIRECTION

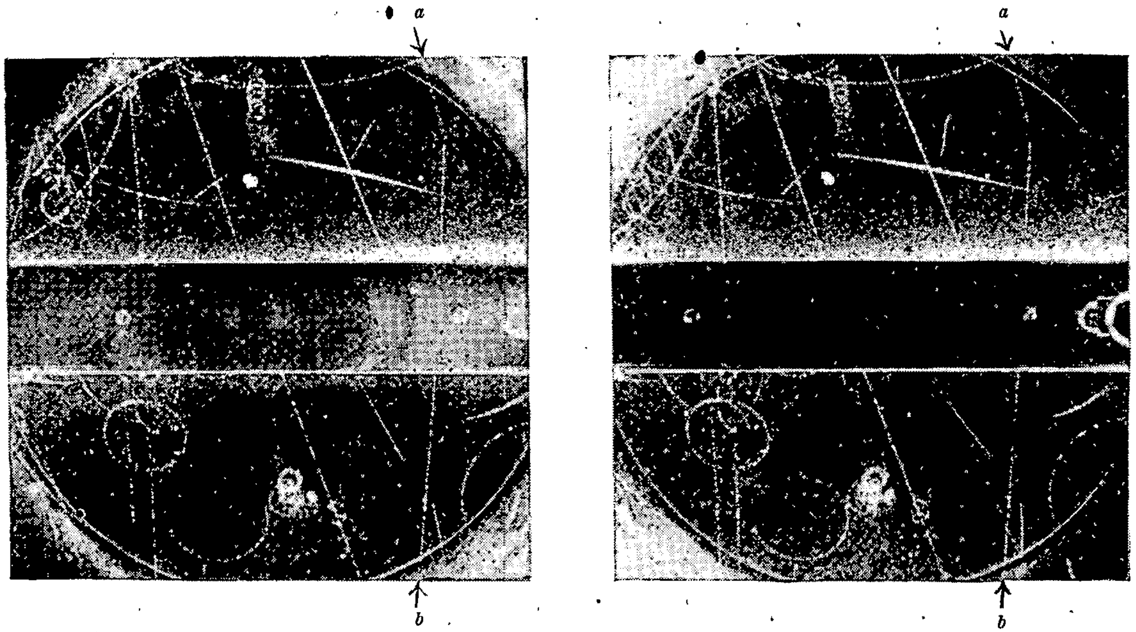

Fig. 2. STEREOSCOPIC PHOTOGRAPHS SHOWING AN UNUSUAL FORK (a b). THE DIRECTION OF THE MAGNETIC FIELD IS SUCH THAT A POSITIVE PARTICLE COMING DOWNWARDS IS DEVIATED IN A CLOCKWISE DIRECTION

The Masses of the Incident Particles

Let us assume that a particle of mass M and initial momentum P is transformed spontaneously into two particles of masses m_1 and m_2, momenta p_1 and p_2 at angles of θ and φ with the direction of the incident particle. Then the following relations must hold :

$$\sqrt{M^2c^4+P^2c^2} = \sqrt{m_1^2c^4+p_1^2c^2} + \sqrt{m_2^2c^4+p_2^2c^2} \quad (1)$$

$$P = p_1 \cos\theta + p_2 \cos\varphi \quad (2)$$

$$p_1 \sin\theta = p_2 \sin\varphi. \quad (3)$$

These general relations may be used to obtain the mass of the incident particle as a function of the assumed masses of the secondary particles.

The value of M must be greater than that obtained by taking the rest masses of the secondary particles as small compared with their momenta ; thus the minimum value $M_{\min}$ is given by the following equation :

$$M_{\min}c^2 = c\sqrt{(p_1+p_2)^2 - P^2}. \quad (4)$$

Applying this equation to the forked track of Fig. 1, after calculating P from the observed values of p_1 and p_2, it is found that $M_{\min}$ is $(770 \pm 200)m$, where m is the mass of the electron. The application of equation (4) to the forked track of Fig. 2, however, after calculating p_2 from the observed values of P and p_1, shows that $M_{\min} = (1{,}700 \pm 150)m$. This value of the mass would require an ionization for the incident particle of twice minimum, which is inconsistent with the observed ionization. We are therefore justified in assuming that the real value of P is greater than the observed value which, as indicated in Table 1, has a large error. If larger values of P are assumed, then $M_{\min}$ is reduced in value. The lowest value of $M_{\min}$ is $(980 \pm 150)m$ if P is $14{\cdot}5 \times 10^8$ eV./c. Beyond this value of P the mass increases slowly with increasing momentum. No choice of incident momentum will bring the mass of the incident particle below 980 m.

In the special case where the incident particle disintegrates transversely into two particles of equal mass m_0, giving a symmetrical fork, equation (1) reduces to the following expression,

$$\frac{M}{m} = \frac{2m_0}{m}\left(1 + \frac{p^2c^2}{m_0^2c^4} \cdot \sin^2\theta\right)^{1/2}, \quad (5)$$

where p is the momentum of each of the secondary particles. Some typical results for different assumed secondary particles, calculated from equation (5), are given in Table 2. On the reasonable assumption that the secondary particles are light or heavy mesons, that is, with masses of $200m$ or $400m$, we find that the incident particle in each photograph has a mass of the order of $1{,}000m$.

TABLE 2. MASS OF INCIDENT PARTICLE AS A FUNCTION OF MASS OF SECONDARY PARTICLE

Photograph	Assumed secondary particle m_0/m	Momentum of observed secondary particle (eV./c.)	Incident particle M/m
1	0	$3{\cdot}5 \times 10^8 \pm 1{\cdot}0 \times 10^8$	770 ± 200
	200	"	870 ± 200
	400	"	1110 ± 150
	1837	"	3750 ± 50
2	0	$7{\cdot}7 \times 10^8 \pm 1{\cdot}0 \times 10^8$	980 ± 150
	200	"	1080 ± 100
	400	"	1280 ± 100
	1837	"	3820 ± 50

Upper values of the masses of the incident particles may also be obtained from the values of the ionization and the momenta. Thus for each of the observed particles in Fig. 1, the ionization is indistinguishable from that of a very fast particle. We conclude, therefore, that $\beta = v/c \gg 0{\cdot}7$. Since the momentum of the incident particle may be found from the observed momenta of the secondary particles, we can apply equation (1) to calculate M. In this way we find $M/m \ll 1{,}600$. Again, since the ionization of the incident particle in Fig. 2 is light, $\beta \gg 0{\cdot}7$, from which it can be shown that $M/m \ll 1200$. This last result, however, must be taken with caution because of the uncertainty in the measured value of the momentum of the incident particle.

One further general comment may be made. This is that the observation of two spontaneous disintegrations in such a small number of penetrating showers suggests that the life-time of the unstable particles is much less than the life-time of the ordinary meson. An approximate value of this life-time may be derived as follows. The probability of an unstable particle of life-time τ_0 decaying in a short distance D is given by

$$p = \frac{D(1 - \beta^2)^{1/2}}{\tau_0\, c\, \beta}. \qquad (6)$$

Since the total number of penetrating particles in the penetrating showers so far observed is certainly less than 50, we must assume that the number of our new unstable particles is unlikely to have been greater than 50. Since one particle of each type has been observed to decay, we can therefore put $p \approx 0{\cdot}02$. Setting $D \approx 30$ cm., and $\beta = 0{\cdot}7$, we find from equation (6) that $\tau_0 = 5{\cdot}0 \times 10^{-8}$ sec.

We shall now discuss possible alternative explanations of the two forks.

Photograph 1. We must examine the alternative possibility of Photograph 1 representing the spontaneous disintegration of a charged particle, coming up from below the chamber, into a charged and an uncharged particle. If we apply the argument which led to equation (4) to this process, it is readily seen that the incident particle would have a minimum mass of 1,280m. Thus the photograph cannot be explained by the decay of a back-scattered ordinary meson. Bearing in mind the general direction of the other particles in the shower, it is thought that assumption of the disintegration of a neutral particle moving downwards into a pair of particles of about equal mass is more probable. Further, it can be stated with some confidence that the observed ionizing particles are unlikely to be protons because the ionization of a proton of momentum $3{\cdot}5 \times 10^8$ eV./c. would be more than four times the observed ionization.

Photograph 2. In this case we must examine the possibility of the photograph representing the spontaneous decay of a neutral particle coming from the right-hand side of the chamber into two charged particles. The result of applying equation (4) to this process is to show that the minimum mass of the neutral particle would be about 3,000m. In view of the fact that the direction of the neutral particle would have to be very different from the direction of the main part of the shower, it is thought that the original assumption of the decay of a charged particle into a charged penetrating particle and an assumed neutral particle is the more probable.

We conclude from all the evidence that Photograph 1 represents the decay of a neutral particle, the mass of which is unlikely to be less than 770m or greater than 1,600m, into the two observed charged particles. Similarly, Photograph 2 represents the disintegration of a charged particle of mass greater than 980m and less than that of a proton into an observed penetrating particle and a neutral particle. It may be noted that no neutral particle of mass 1,000m has yet been observed; a charged particle of mass 990m ± 12 per cent has, however, been observed by Leprince-Ringuet and L'héritier[2].

Peculiar cloud-chamber photographs taken by Jánossy, Rochester and Broadbent[3] and by Daudin[4] may be other examples of Photograph 2.

It is a pleasure to record our thanks to Prof. P. M. S. Blackett for the keen interest he has taken in this investigation and for the benefit of numerous stimulating discussions. We also wish to acknowledge the help given us by Prof. L. Rosenfeld, Mr. J. Hamilton and Mr. H. Y. Tzu of the Department of Theoretical Physics, University of Manchester. We are indebted to Mr. S. K. Runcorn for his assistance in running the cloud chamber in the early stages of the work.

THE GRASSHOPPER PROBLEM IN NORTH AMERICA

By Dr. B. P. UVAROV, C.M.G.

Anti-Locust Research Centre, British Museum (Natural History)

OFFICIAL figures compiled by the Division of Grasshopper Control of the United States Bureau of Entomology show that in the ten-year period 1936–46, crops to the value of 424,563,614 dollars were destroyed by grasshoppers, and 26,088,211 dollars was spent on control measures. No similar statistics are available for Canada, where the general situation with regard to grasshoppers is similar. The annual figures for the same period show considerable fluctuation, apparently dependent on natural variations in grasshopper populations; but they do not suggest any general downward trend which might be interpreted as a cumulative result of persistent artificial control measures. It must be stressed that these measures are unquestionably very successful so far as the protection of standing crops of the year is concerned, and the organisation of control, based on close co-operation of Federal and State agencies and the farmers, leaves little to be desired. Both the organisation and the technique of artificial control are being continually perfected, and it is estimated that, on the average, each dollar spent on grasshopper control serves to save crops to the value of 35 dollars. This is a remarkable achievement, and a large share of credit for it belongs to the Division of Grasshopper Control, admirably organised and run by Dr. Claude Wakeland and his staff. Nevertheless, it is clear that the protection of crops by direct control methods cannot be relaxed, and efforts on an ever-increasing scale will have to continue indefinitely. The policy of direct control is a palliative which cannot lead towards a lasting solution of the grasshopper problem in the North American continent.

This state of affairs has been realized by entomologists of the United States and Canada for some time, and their views were forcibly expressed in the following resolution adopted at a session of the Committee on Grasshopper Research at Lincoln, Nebraska, in 1946: "Millions of dollars have been appropriated and spent during the past twenty years by state, provincial, federal and dominion agencies for materials and labour for the applied control of grasshoppers. During the same period, the amount of money spent on research for a solution of the grasshopper problem has been woefully inadequate.

We are convinced that each million dollars spent on grasshopper research now will save hundreds of millions to the people of the United States and Canada in future emergencies." The Lincoln Conference elaborated a programme of research and recommended that such research should be co-ordinated for the whole continent by a permanent Committee on Grasshopper Research of the American Association of Economic Entomologists, through a 'research co-ordinator' whose duty it would be to stimulate research, to assist it and to ensure the co-operation between different research agencies. The important practical question of establishing and financing the 'co-ordinatorship' remained, however, unsolved.

The next session of the Committee on Grasshopper Research was held at St. Paul, Minnesota, in March 1947, and I had the privilege of taking part in the discussions. Afterwards, I was able to visit several of the most important centres of grasshopper research in the United States and Canada and to study their work on the spot. The impressions gained during this short visit may have been incorrect, and are certainly incomplete; but they are of considerable general interest as an illustration of a research policy diverted from its ultimate objective by temporary influences.

All programmes of grasshopper research both in the United States and in Canada are dominated by the need to produce immediate practical results, on which year-to-year financing of research depends. Therefore, two items of research are in the foreground. One is the testing of new insecticides, which are continually appearing on the market. Little fundamental research on insecticide action is in evidence, but purely empirical evaluation of effectiveness and cost take a vast amount of time and energy of research workers. It was somewhat disconcerting to see almost the whole entomological staff of the Federal Grasshopper Research Section occupied for weeks in carrying out field-tests of new insecticides, without any technical assistants or labour. The explanation was the very high cost of labour; but the use of qualified research workers for actual field operations appeared a very questionable measure of economy.

The second problem absorbing research workers is grasshopper survey. Systematic surveys of grasshopper populations were introduced more than ten years ago, and since then three annual surveys (nymphal, adult and eggs) are carried out regularly over all States subject to infestation. Survey methods, sampling technique and the analysis of the data are very elaborate and are standardized throughout, so that, theoretically, one would expect the surveys to produce a vast accumulation of data of great value for an analysis of population trends and the factors regulating populations. Unfortunately, the surveys are primarily intended to provide a statistical basis for the assessment of the expected infestation and for the calculation of quantities of control materials. The value of the survey data for population studies is undoubtedly very great; but the execution of surveys and purely statistical computation of their results appear to occupy practically the whole time of the survey personnel. It was instructive to see how an admirably conceived and perfectly organised machinery for collecting scientific data of great value has enslaved its creators and has made it almost impossible for them to do anything beyond routine work. The amount of the accumulated data is now so great that it would take a team of research workers several years to analyse this material. There is no doubt that such an analysis would provide information on the sources of grasshopper outbreaks and on the factors controlling them; this information would form a basis for formulating a long-range policy directed towards a lasting prevention of grasshopper outbreaks, instead of annual campaigns achieving only temporary relief; but it is apparently very difficult to make the administration realize the need for any expenditure that does not promise immediate return.

The soundness of the idea of grasshopper prevention was freely admitted by American and Canadian colleagues, but they were clearly of the opinion that, under present conditions, it would be futile to contemplate such a policy, which requires planning and execution on a continental scale. This close dependence of an entomological problem on the social structure of the country is most strikingly illustrated by the example of the grasshopper situation in the Phœnix valley of Arizona. It is a wide irrigated plain where cotton cultivation prevailed in the past; but during the Second World War a rise in the price of alfalfa seed caused a great extension of the latter crop. Irrigated alfalfa fields in a semi-desert climate of Arizona provided ideal conditions for *Melanoplus mexicanus* and enabled it to produce up to three generations in a year instead of the normal one. A most serious infestation by this species has developed, and repeated applications of control methods are required to save the crop. Even a cursory examination of the area has suggested that some less well-cultivated fields, with patches of grass, may be the sources of infestation, and a general application of certain cultivation methods may have a far-reaching effect. The possibility of this approach was admitted, but it was pointed out that it will never be possible to induce all growers of alfalfa to adopt improved methods, particularly because in that area the cultivation of alfalfa on such a large scale is due mainly to the high and possibly only temporary profits. Should the price fall, alfalfa will be abandoned in favour of another crop. Under such conditions, any long-range policy is useless to contemplate, and palliatives must continue to be employed. Sooner or later, they may become too costly in relation to the crop value, and the problem of long-range prevention will inevitably arise. It might be a sound policy at least to commence research in that direction before the crisis becomes acute; but it does not appear possible to expect that the necessary funds would be obtainable for a long-range research which does not promise an immediate profit.

Apart from the enforced wrong emphasis in the research programmes, they suffer from a lack of co-ordination. A striking fact is that although certain grasshoppers, notably *Melanoplus differentialis*, are very extensively used in universities as laboratory animals, such research as is carried out in universities is entirely disconnected from field-work executed by the federal grasshopper research agencies, by experimental stations and by the agencies engaged in grasshopper surveys. At the meetings of the Committee on Grasshopper Research, university research workers were conspicuous by their absence, with very few exceptions. As a result, field investigators are often very backward in their approach to the problem, while university workers do not know of the existence of a large number of problems of grasshopper biology which arise in the field but can only be solved in the laboratory.

The need for co-ordinating all grasshopper research has been repeatedly stressed by the Committee on Grasshopper Research, but the impression was that this is an aspiration rather than a demand for a practical measure. It would be natural to suggest that co-ordination of grasshopper research might be organised, or at least financed, jointly by the Governments of the two North American countries, but somehow this appeared to be impracticable.

In spite of all handicaps, American entomologists are making great strides in the study of the grasshopper problem. Unfortunately, their achievements are insufficiently known, since surprisingly little has been published on the subject, mainly because the routine work leaves no time for analysing and summarizing the results. It was even more surprising to hear that many important papers have been ready and waiting for publication for some years. Lack of funds as an explanation did not sound very convincing for a European visiting the United States. The Committee on Grasshopper Research has passed a very strong recommendation that the analysis of accumulated data and the publication of results should be speeded up; but it remains to be seen what the official reaction will be.

It is impossible here to discuss details which would be of interest only to specialists, who have a great deal to learn from the experience of American colleagues, particularly with regard to the technique and the organisation of grasshopper control. A much wider interest is attached to the general aspects of the North American grasshopper problem and its treatment. There is no doubt whatever that the problem is a man-made one, and it reached its great economic importance as a result of land development which was rapid, extensive and unscientific. A rapid expansion of unplanned agriculture in the North American continent has created exceptionally favourable conditions for various insect pests and for grasshoppers in particular. An analogous situation is rapidly developing in Australia, and it is only a matter of time before Africa will be faced with similar results of extensive agricultural development. There is in Africa a vast and varied grasshopper fauna, many members of which will undoubtedly develop into dangerous pests as soon as suitable soil conditions and abundant food are provided for them by the clearing of forests and by mechanized agriculture. At present, African development is threatened by locust plagues, which are a serious factor, but a periodical one; grasshopper plagues, although less spectacular than locust invasions, will be much more serious in their aggregate effects because they tend to be perennial, as the example of North America shows. Anti-locust policy in Africa is developing on the lines of prevention, and it became possible to formulate such policy only after some twenty years of international research. It will take a long time to study the possible effects of mechanized agriculture on native grasshoppers, and it is therefore not too early to consider commencing such studies. The alternative is to do nothing until the danger becomes imminent, by which time it may be too late for any measures of prevention, and perennial artificial control will be required. Again, the American example shows that such control is very expensive and only highly remunerative crops can stand the cost. Agricultural development of Africa is now being planned on a vast scale, and it may be wise not to forget possible handicaps.

ATMOSPHERIC TURBULENCE

MANY workers in atmospheric turbulence probably believe the subject to be more readily capable of formal and exact development than some other branches of dynamical meteorology, a belief deriving from a certain measure of success already attained. But that this success is rather slight is evident when one considers that there is still only slight understanding of turbulence in isothermal flow such as occurs in wind tunnels, pipes, etc., while the atmospheric problems are complicated by the existence of buoyancy forces, positive or negative, by the earth's rotation, and, over the oceans, by the form, of the surface being dependent on the air motion itself. Again, there is a very considerable difference in scale between laboratory and atmospheric flow; but this difference may well be ultimately profitable to an improved understanding of turbulence on all scales—solar, terrestrial (atmospheric and oceanic), and laboratory.

G. I. Taylor effectively established the subject of atmospheric turbulence in his classical paper of 1915. From observations of temperature on the Eiffel Tower and by kite over the Newfoundland Grand Banks, and from Dobson's observations of wind speed and direction in the first kilometre or so over Salisbury Plain, Taylor deduced that the turbulence of the lower atmosphere resulted in an effective coefficient of diffusion of heat or of momentum some 10^4–10^6 times greater than the value for molecular diffusion, the ratio increasing with the wind speed and the lapse-rate of temperature. The equations of heat or momentum transport by which these results were obtained were solved by assuming the turbulent diffusivity constant through the layer concerned, whereas on any simplified picture of eddy motion a variation with height appeared probable; and this variation was involved in the next major advance in the subject early in the last decade. The advance was derived from Prandtl's application of mixing-length ideas growing out of earlier work by Taylor and Schmidt, the mixing-length being an analogue in eddy motion of the mean free path of molecular theory and connoting the mean length of path over which turbulent elements move between birth and extinction, that is, between acquiring and losing a velocity different from that of the mean motion at the levels in question. Prandtl assumed that near a boundary the mixing-length increased linearly with distance from the boundary, and by assuming further that the turbulent elements conserved their momentum during motion (that is, pressure field of no immediate consequence) he deduced that the mean velocity should increase with the logarithm of the distance from the boundary in the region of negligible variation of turbulent shearing stress. This result was in accord with observations in the laboratory for a very wide range of Reynolds number, and in the first 10 m. or so of the atmosphere when in near-neutral static equilibrium. The mixing-length distance relation, more or less confirmed by this agreement of theory with observation, implied that turbulent diffusivity increased linearly with distance from the boundary and was given directly, for momentum transfer at least, from observations of the velocity profile.

Early in the 1920's, L. F. Richardson had examined the effect of static stability on the rate of growth or decay of turbulence. He showed that the rate of production of turbulent energy due to a velocity gradient would compensate the rate of decay due to the work done by eddies against (negative) buoyancy forces, provided the ratio of the square of the vertical gradient of mean velocity to the difference between the adiabatic and actual lapse-rates of mean temperature exceeded a certain critical magnitude. This criterion is only now receiving the attention and application which it merits.

It is to be noted that the above achievements are expressed in the main in terms of the bulk properties of the medium (mean speed and gradients of mean speed and of temperature, etc.), a desirable feature for a ready assessment of the diffusive properties of a given field of mean flow, but inadequate for an understanding of the mechanics of turbulence. Progress in the latter has been rather slight, though much experimental work has been done in the wind tunnel on the measurement of turbulent energy and of its spectrum, and on the correlation between various turbulent velocity components. This has been allied with a promising theoretical treatment of the statistical mechanics of isotropic turbulence, initiated by Taylor in 1935. A little knowledge has been gained of the statistics of atmospheric turbulence in the lower atmosphere, notably by Giblett, Scrase and Best in Great Britain, but there is very little information for the free atmosphere.

This was the background against which the Geophysical Discussion at the Royal Astronomical Society on "Atmospheric Turbulence" was held on October 24. Prof. O. G. Sutton opened the discussion by stressing the alternative approaches to the subject, the approach through the study of bulk properties on one hand and through the study of the internal structure of the fluid on the other, recapitulating the history of the subject and some of the more readily observed characteristics of atmospheric turbulence in illustration. A potentially profitable approach on the structural side was made by Taylor in 1922 in providing a relation between the diffusion of an entity and the correlation between the eddy velocities of a given element of fluid at increasing intervals of time. Sutton developed this treatment by an empirical formulation of the correlation coefficient (direct observations of the correlation coefficient would be very difficult and an *a priori* derivation presupposes a basic understanding of turbulence), and he deduced the rate of transfer of matter (evaporation) from a plane boundary in a turbulent flow, obtaining good agreement with observations for both matter and heat transfer in the laboratory for aerodynamically smooth flow, that is, flow in which the molecular viscosity is responsible for momentum transfer at the boundary itself. This treatment remains to be generalized for aerodynamically rough flow, that is, flow in which the geometrical roughness of the boundary is a controlling factor, and for an atmosphere statically stable or unstable. Sutton also pointed out some of the major meteorological problems of a larger scale requiring investigation and solution, such as the temperature and humidity distribution in the layer which is responsible for the propagation of short radio waves over the earth's surface (see *Nature*, **157**, 860; 1946), and the structure and distribution throughout the troposphere of gusts which on occasion may be a serious hazard for aircraft.

Prof. P. A. Sheppard spoke of his simultaneous measurements of surface drag and the accompanying velocity profile in the air. In the laboratory the mean velocity u at distance z from a boundary is related with the drag τ_0 at the boundary by

$$u = \frac{(\tau_0/\rho)^{1/2}}{k}\left[\log_e\left\{\frac{(\tau_0/\rho)^{1/2}z}{\nu}\right\} + 1{\cdot}75\right]$$

. . . aerodynamically smooth flow,

or

$$u = \frac{(\tau_0/\rho)^{1/2}}{k}\log_e\left(\frac{z}{z_0}\right)$$

. . . aerodynamically rough flow,

where k (about 0·40) is the constant of proportionality between mixing length and distance referred to above, ρ is the fluid density, ν the kinematic viscosity and z_0 a length characterizing the roughness of the boundary. For either type of flow the turbulent diffusivity $K\left(=\frac{\tau_0/\rho}{du/dz}\right)$ is given by

$$K = (\tau_0/\rho)^{1/2}kz,$$

where τ_0/ρ may be obtained from observations of the velocity at two heights. Sheppard's observations were made to determine whether the same relation between profile and drag held in the lower atmosphere, or, alternatively stated, to determine the value of k there. The result, for a moderately unstable atmosphere, was $k = 0{\cdot}45$, in very reasonable agreement with the laboratory value in view of the instability which would enhance k. There was also found to be a significant departure from linearity between mixing-length and height in the sense of larger mixing-lengths at the upper levels of observation—again reasonable in view of the instability arising from buoyancy. Correspondingly, one might expect a departure from linearity in the opposite sense in stable conditions. Such departures must be reflected in corresponding departures from the logarithmic profile of wind velocity. Further, if the mixing-length is the same for any entity diffusing vertically, the profile of that entity should show a variation with stability (Richardson's Number is likely to be the relevant parameter) similar to that for wind velocity. Evidence of such variation was shown in the profiles of wind speed, temperature and vapour pressure obtained by various workers in the first 15 m. or so of the atmosphere; entities increased or decreased less rapidly than the logarithm of the height in unstable conditions, and more rapidly than this in stable conditions. Such profiles imply that the turbulent diffusivity increases more rapidly than the height in unstable conditions and less rapidly than the height in stable conditions. Up to what level these relations apply is not yet known—the increases cannot continue indefinitely.

Mr. F. Pasquill spoke on turbulence in agricultural meteorology and dealt first with the loss of water from soil and crops by turbulent diffusion. If the diffusivity for matter is the same as for momentum, the former is immediately deducible from a velocity profile; and the rate of evaporation E in a steady state (vertical flux of water vapour independent of height) is then obtainable from the vertical gradient of specific humidity $q(E = K/\rho . dq/dz)$. Pasquill's results from observations of the velocity and humidity profiles in the first 2 m. over grass gave quite encouraging agreement with the loss of water determined by soil sampling before and after the profiles had been determined, though the results of the soil sampling were a little ambiguous. Another agricultural application related to the dispersal of wind-borne spores, a problem first tackled by Schmidt many years ago. The spores are dispersed by turbulence as they travel down-wind and are simultaneously deposited on the ground due to fall under gravity—a procedure analogous to the transport of silt in a river or estuary. Pasquill has calculated the rate of deposition at various distances down-wind of the source under given conditions, and obtains quite reasonable agreement with the rather meagre experimental data available.

Mr. K. L. Calder presented some very striking evidence of the applicability of Prandtl's expression for the eddy diffusivity in an isothermal boundary layer to the problem of the diffusion of gas and smoke emitted into the atmosphere near the ground along a line normal to the wind direction. The treatment takes account of the roughness of the underlying surface and gives excellent agreement with a large number of observed concentrations of gas and smoke.

Mr. E. L. Deacon showed a slide of velocity gradients, taken between 2 m. and 4 m. at a given site in various wind speeds and static stabilities, plotted against the Richardson Number for the same height-interval and times of observations. The high correlation shown gave strong support to the growing realization of the importance of Richardson's parameter in atmospheric turbulence.

The 'structural' approach to the study of atmospheric turbulence, either in terms of Prandtl's mixing-length or of Sutton's application of the Taylor correlation coefficient, has been essentially empirical. The mixing-length as used by Prandtl is indeed an idealized concept corresponding to no measurable property of the turbulence itself; it is rather a parameter with the dimension of length which appears from a suitable transformation of the turbulent flux equation. Sutton ascribed the difficulty of developing an *a priori* treatment of turbulence to the non-linear form of the Navier–Stokes equations and saw little hope of overcoming this difficulty, but Mr. G. K. Batchelor ended the discussion on a more hopeful note. He instanced the appreciable success of the fundamental theory launched by Taylor in 1935 to deal with the correlations between eddy velocities at points across and along the direction of mean flow when the turbulence is isotropic, and with the decay of such turbulence in a free stream. The theory is still in vigorous development, and may be expected, sooner or later, to provide better understanding of atmospheric problems.

P. A. SHEPPARD

NEWS and VIEWS

Students in British Universities

IN NATURE of December 6, in the course of an article on "University Expansion in Great Britain", a statement is attributed to Lord Simon to the effect that the output of arts graduates has risen more rapidly than that of science graduates, due to relatively greater ease of expansion on the arts side. Against this remark should be set the figures for university 'populations' given in a written answer by Sir Stafford Cripps in the House of Commons (*Hansard*, House of Commons, December 1). The total number of full-time students at university institutions in Great Britain for the autumn term 1947 was 76,764, compared with 50,246 for the academic year 1938–39. Analysing these totals by faculties, the figures for arts students were 34,200 and 22,512 respectively. The figures under pure science are 14,520 for 1947 and 7,767 for 1938–39; and an approximate doubling is also shown under technology (10,143 and 5,288) and under agriculture (2,337 and 1,043). Thus, whatever may be the present position with regard to the employment of arts graduates, the actual numbers of students in the arts faculties and in the science and technological faculties now in British universities have increased by about the same numbers since 1938–39, namely, 11,688 and 12,902 respectively; but whereas this represents an increase in the arts faculties of 52 per cent, in the science and technology faculties the increase is 91·5 per cent.

Some interesting figures are also given regarding the numbers of students now at the various universities of Britain as compared with the figures for the year 1938–39. Taking the larger universities only, they are as follow, the number in parenthesis being that for the last pre-war year: Birmingham, 2,975 (1,433); Bristol, 1,902 (1,005); Cambridge, 6,943 (5,931); Durham, 3,773 (1,709); Leeds, 2,888 (1,757); Liverpool, 2,943 (2,055); London, 15,789 (13,191); Manchester, 4,632 (2,462); Nottingham, 1,679 (582); Oxford, 7,500 (5,023); Reading, 990 (584); Sheffield, 1,670 (767); Wales, 4,654 (2,779); Aberdeen, 2,007 (1,211); Edinburgh, 4,904 (3,205); Glasgow, 7,073 (4,690); St. Andrews, 1,811 (928). The increases have thus been well spread over the whole country, though the biggest percentage increases are shown by some of the smaller institutions.

Annals of Botany: Prof. V. H. Blackman

READERS of the *Annals of Botany* will have seen with an element of regret that since September 30 Prof. V. H. Blackman has ceased to be editor. Prof. W. H. Pearsall, who succeeds him, is pre-eminently well qualified to do so, and as former editor of the *Journal of Ecology* is well known to many botanical authors. It is, however, fitting to record the very great debt which the botanical world owes to Prof. Blackman who, for more than twenty-five years, has borne with equanimity, kindliness and wisdom the editorship of one of the most influential botanical journals in the world. Almost every working botanist in Great Britain, and many from overseas, have at some time in their lives come under his influence, and the blue pencil has always been administered so graciously that a permanent friendship with the author has generally resulted in spite of compulsory improvement to literary style. It is greatly to be hoped that Prof. Blackman's influence on botany as a whole, and on younger botanists in particular, will continue to be felt for many years in other ways after the very considerable burden of the editorship has been lifted from him.

Sir Evelyn Shaw, K.C.V.O., and the Exhibition of 1851 Scholars

AN interesting informal gathering took place at the offices of the Royal Commission for the Exhibition of 1851 on December 5. A number of former '1851' scholars made a presentation to Sir Evelyn Shaw, who has recently retired from the post of secretary after forty-three years' service with the Royal Commission. Since the awards were inaugurated in 1891, there have been more than five hundred scholars from Great Britain and all parts of the Empire. Most of them have studied in Great Britain and have been grateful for the friendly help given to them by Sir Evelyn Shaw. The presentation consisted of an album containing the signed photographs of 330 'old scholars' from all parts of the world, and a gold coin, dated 40 B.C. and bearing the portraits of Marc Antony and the young Octavius, chosen by Sir Evelyn for his collection. Sir Robert Robinson, chairman of the Science Scholarships Committee of the Royal Commission, and himself a former '1851' scholar, was unavoidably prevented from being present, and sent a goodwill message. The presentation was made on behalf of his fellow scholars by Prof. E. N. da C. Andrade, who expressed the esteem and affection felt for Sir Evelyn by all who had come into contact with him.

Trees and Shrubs as Animal Fodder

THE extent to which animals are dependent on shrubs and trees for fodder is probably not fully realized by those accustomed to associate grazing with true grass or grass–legume pastures, ranges or steppes. The information, however, provided in Joint Publication No. 10, "The Use and Misuse of Shrubs and Trees as Fodder", published by three of the Imperial Agricultural Bureaux (Pastures and Field Crops, Forestry, and Animal Nutrition, respectively) leaves no doubt as to the magnitude of the subject. Over large areas, particularly those with semi-arid climates, in Australia, Africa, India, the U.S.S.R., United States of America and lands in the Mediterranean region, woody plants provide the chief source of food for the numerous low-grade animals kept for the wool, hides and even meat they produce. Most of these regions suffer from gross over-stocking, with a resultant deterioration in the vegetative cover, which in its turn gives rise to serious soil erosion. The problems are numerous, and their solution by no means similar in different parts of the world; but the breeding of better-class animals and a reduction in their numbers should both check the soil erosion and make it economically advantageous to grow improved types of fodder. The best type of management of shrub-tree associations has yet to be found. Experiences with restricted seasonal grazing, reclamation work by re-seeding, and direct shrub cultivation are described and the problems of forest grazing discussed. Bush encroachment on grazing land offers serious difficulty in some countries, and various control measures are being tried for the eradication of undesirable species. As regards nutritive value, the chemical composition and digestibility of some thousand samples of shrubs and trees are tabulated; it is significant that, compared with grassland, the values fluctuate little with season. so that they are of special value in times of drought when indigenous grasses are at their lowest nutritive level. The publication, which contains seventy illustrations, can be obtained from the Imperial Agricultural Bureaux, Central Sales Branch, Penglais, Aberystwyth, Great Britain (9*s*. net).

Agriculture in Northern Ireland

IN 1943 an Agricultural Enquiry Committee was set up to report on the future of agriculture in Northern Ireland, and interim reports on transport and rural housing appeared in 1943 and 1944. The full report has now been published (H.M. Stationery Office. 3*s*. 6*d*. net) and is divided into five main sections, dealing respectively with agricultural policy and production, marketing and processing, education and research, services ancillary to agriculture, and social conditions and the agricultural community. In view of its geographical position and climate, concentration on the production of livestock and livestock products is recommended as a long-term policy. Closely correlated with this is the need for improvement in the grassland, and to carry this out, the establishment of an experimental farm in County Fermanagh is suggested, and the periodic breaking up of the pastures strongly advocated. As regards marketing, the Committee is of the opinion that the Government should continue its policy of guaranteed prices for all major farm products, such prices being based on those considered necessary to call forth the production required, the Exchequer bearing the cost of any subsidies that may be needed. Considerable reorganisation is proposed in the sphere of education, while as regards research, investigations on the nutritive value of grassland, animal breeding and veterinary problems are of special importance to bring the work into line with the general agricultural policy outlined above. Adequate ancillary services are an essential feature, and attention is directed to the need for a satisfactory system of land tenure, and better electricity and water supplies, drainage and sewage schemes. The concluding section of the report puts forward a proposal for the establishment of a Central Agricultural Council, based on existing organisations, which should act as a corporate body for the promotion of the welfare of the agricultural industry and the improvement of social conditions for the rural population.

The Scottish Plant Breeding Station

THE twenty-sixth annual report of the director of the Scottish Society for Research in Plant Breeding provides much evidence of the value of research for agriculture. The Society is in a healthy state, having received a large number of subscription members during the year. New varieties of oats, barley, swedes, grasses and kales are either in commerce or will shortly be released. Three lines of work at the Station are of particular interest. The investigations upon virus diseases and blight of the potato have reached the stage at which the breeding of immune or resistant varieties may be directed. Dr. Gregor has shown that local races of grasses are often of considerable value as source material for breeding in the same way as the ancient local strains of oats and barley were of advantage in the eighteenth century. The genecological studies originally made upon *Plantago* are therefore bearing fruit in agriculture. The director, Mr. W. Robb, has been selecting suitable strains from among more than 15,000 hybrids of oats with the view of combining stiff straw, and freedom from lodging, with high yields. As the result of negotiations between the Society and other bodies it will be possible to enlarge the grounds and the activities in the near future.

An Electric Heater for Flasks

AN electric 'mantle' for the heating of flasks, termed an 'Isomantle', has recently been introduced into Great Britain by Messrs. Towers and Co., Ltd., of Widnes. It consists essentially of a tough, double-walled, glass-cloth shroud, hemispherical in shape and carrying a nichrome/glass-cloth heating-element in close proximity to the inner wall. A packing of glass-wool provides efficient thermal insulation, and the whole unit is carried in a neat aluminium cradle which may either be placed directly on the bench or supported by a retort stand. Temperature is regulated by a series resistance or, more effectively on an A.C. supply, by a device named the 'Simmerstat', which gives continuous and accurate control of heat from zero to a maximum sufficient to boil liquids at 300–350° C. Laboratory tests show that an 'Isomantle' provides a really safe and efficient method of heating liquids, particularly for operations such as routine solvent extraction. Flask breakage will be reduced to a minimum, and the large heating-area promotes uniform boiling. Deliberate efforts to induce the 'bumping' of boiling liquids were quite unsuccessful. A range of sizes from 100 to 5,000 ml. is being prepared; it is to be hoped that the manufacturers may eventually find it possible to 'tailor' jackets of other shapes for special purposes.

Research in the Jewellery Industry

The first annual report of the Design and Research Centre for the Gold, Silver and Jewellery Industries has been issued (Goldsmiths' Hall, Foster Lane, London, E.C.2); the Centre was inaugurated on October 1, 1946. After referring briefly to the initiation of market and consumer research, the training of designers, including the provision of refresher courses and the plans for development of the library and reading room and information service, the report deals with the plans of the research section. Prof. R. S. Hutton was originally appointed honorary acting director of research, and an Advisory Research Committee has formulated a research programme and initiated investigations on tarnish-resisting silver at the Metallurgical Laboratory, University of Cambridge, and on polishing processes, temper-hardened silver, coloured patina and other metal finishes at the Sir John Cass Institute, London. Dr. C. E. Garden was appointed director of research and took up his duties on June 2, 1947, and an industrial liaison officer has also been appointed. An information bulletin is being issued, and a research laboratory is being established at Goldsmiths' Hall, London.

Californian Academy of Sciences

In the annual report of the Californian Academy of Sciences for the year ending December 31, 1946, the president, refers to the decision of the trustees to proceed with a campaign for raising funds which will make possible the construction of a planetarium adjacent to the Academy's buildings in Golden Gate Park. It is also planned to build an addition to the African Hall, an auditorium and additional housing to relieve the over-crowding of several of the departments. The director, Dr. R. C. Miller, refers in his report to the resumption of field-work by nine members of the Museum staff, who made eleven field trips to points ranging from Newport, Oregon, to Acapulco, Mexico, and from the seashore to the High Sierra. Many accessions to the departmental collections were made during the year, and the director reports briefly on the work of the Academy's Committee of Latent Natural Resources, established in January 1942, to organise research relating to the existing national emergency. The work of the Committee was carried on chiefly by correspondence; the Committee has had a leavening influence far beyond the range of its immediate activities, which included the location of strategic minerals, the resources of the sea for war-time economy, black glass for mirrors for navigating instruments and tuna fisheries. The Committee is being retained as a stand-by committee for consultation on similar problems as need may arise.

University News

A chair of genetics is to be established in the Faculty of Science, University of Birmingham.

Mr. Charles R. Morris, formerly fellow of Balliol College and later Under-Secretary at the Ministry of Production, has been nominated as vice-chancellor of the University of Leeds in succession to Dr. Mouat Jones, who retires on October 1, 1948.

Mr. R. L. Goodstein, lecturer in mathematics in the University of Reading, has been appointed professor of mathematics in University College, Leicester.

Dr. F. E. King, lecturer in chemistry in the University of Oxford, has been appointed Sir Jesse Boot professor of chemistry in University College, Nottingham.

Announcements

We regret to announce the deaths of Earl Baldwin of Bewdley, K.G., P.C., F.R.S., on December 14, aged eighty; Dr. Charles Bolton, C.B.E., F.R.S., consulting physician to University College Hospital, London, on December 6, aged seventy-four; and the Right Hon. Lord Rayleigh, F.R.S., on December 13, aged seventy-two.

Prof. A. E. Muskett, professor of mycology and plant pathology in the Queen's University of Belfast, has been elected president for 1948 of the British Mycological Society.

The Atomic Scientists News, the journal of the Atomic Scientists' Association (limited by guarantee), issued approximately monthly, has hitherto only been available to members of the Association. To enable libraries and institutions, and other individuals who do not wish to join the Association, to obtain copies, a subscription scheme has been started. The subscription is 10*s.* 6*d.* a year, and further particulars are obtainable from the editor, Dr. C. H. Westcott, Physics Department, University, Edgbaston, Birmingham, 15.

The international journal of cytology *Chromosoma* was founded by Dr. Hans Bauer, of the Kaiser-Wilhelm Institut für Biologie in Berlin Dahlem, in 1939. It completed its second volume during the War, the last issue appearing in 1944. Its publication has been resumed by the Springer-Verlag, now in Vienna, with a double number (Volume 3) dated August 1947. This number contains papers by Seiler, Geitler, Le Calvez, Schrader and others on many aspects of chromosome behaviour in plants, animals and protista.

An exhibition, "Highways of the Air", is being arranged by the Royal Geographical Society, in co-operation with the Ministry of Civil Aviation, the British Airline Corporations and the Ministry of Education, at the Society's house in Kensington Gore, London, S.W.7, during December 22–January 15; it will be open from 11 a.m. to 5 p.m. on weekdays (except Christmas Day and Boxing Day) free of charge. The exhibition has been planned against the background of the air-age geography and the development of civil airways.

Electron Microscopy of Bacteria

BACTERIA have usually been prepared for observation in the electron microscope by growth in liquid media, a drop of the suspension being allowed to dry on a collodion-covered specimen grid. Smiles[1] has employed an adaptation of the impression technique used in optical microscopy for obtaining material from a surface culture: a glass slide pressed on to the agar removes a film of bacteria, which is allowed to dry partially, and then removed by stripping with a collodion film. Hillier and Baker[2] have described a more direct method, in which the collodion film is formed on the agar surface and then floated off in water. Unfortunately, most bacteria, however mounted, prove to be too opaque to an electron beam of the energy usually employed (50–60 kV.) to show appreciable internal structure.

In studying the morphology of avian tubercle bacilli, which, in certain stages of development, we find to be less dense to electrons than most bacteria, we found it impossible to strip them from the Löwenstein and blood-agar surfaces on which they are normally grown. Two methods have been devised by which intact films can consistently be obtained. In the first, a thin coating of glycerine-agar is spread on the surface of the Löwenstein medium and the bacterial inoculum placed on this. After sufficient growth has developed, a 1 per cent solution of collodion is flowed over the surface, allowed to dry, and removed by immersion in water. Alternatively, a square of the Löwenstein medium, at the required stage of growth, is inverted and the surface pressed firmly for a few seconds on to a glycerine agar surface, so that the culture is transferred from the one to the other. It may afterwards be removed from the latter as before by stripping on a collodion film. In either case the specimen grids are then placed on the stripped film, and both removed and mounted in the usual way. The resulting electron micrographs show a richness and clarity of internal structure not otherwise obtainable (Figs. 1–4). Before spreading the collodion film on the culture, it is fixed by exposure for 5 min. to the vapour of 2 per cent osmic acid. As a further precaution against infection, a 5 per cent solution of formalin is employed for floating off the collodion films, which are then washed in distilled water before mounting. Fixation in formalin vapour proved unsatisfactory in that the films could not afterwards be stripped at all.

An interpretation of the results obtained at different stages in the life of a culture will be published elsewhere.

A New Isotope of Tungsten

A SEARCH for tungsten radio-isotopes was made using a 5-mil tantalum foil which had received 80 micro-ampere-hours bombardment with approximately 20 MeV. deuterons from the 60-in. Crocker Laboratory cyclotron. The foil was dissolved in nitric acid containing five per cent of hydrofluoric acid. A few milligrams of tungsten carrier was added, and after removal of hydrofluoric acid by fuming with sulphuric acid, the tantalum was precipitated by sodium hydroxide and the precipitate digested with hot alkali. Tungsten was precipitated from the alkaline solution by boiling with excess nitric acid. The procedure was repeated until the tantalum-scavenging carrier precipitates were inactive.

The tungsten fraction contained a previously unreported, single radioactivity of half-life 140 ± 2 days, emitting electrons, X-rays and gamma-rays. The radiations were studied using aluminium, beryllium and lead absorbers, measurements being made with an 'end-on' type Geiger – Müller counter with a 2·7 mgm./cm.^{2} mica window, and filled with 10 cm. argon and 0·5 cm. alcohol. The radiations had the following characteristics.

(1) Electrons of range ∼ 11 mgm./cm.^{2}, corresponding to an energy of about 90 keV. The range was determined by resolution of the aluminium absorption curve (Fig. 1) and by direct measurement using thin beryllium absorbers. The absorption of the soft X-ray background was measured in aluminium after removal of electrons by a 14 mgm./cm.^{2} beryllium absorber.

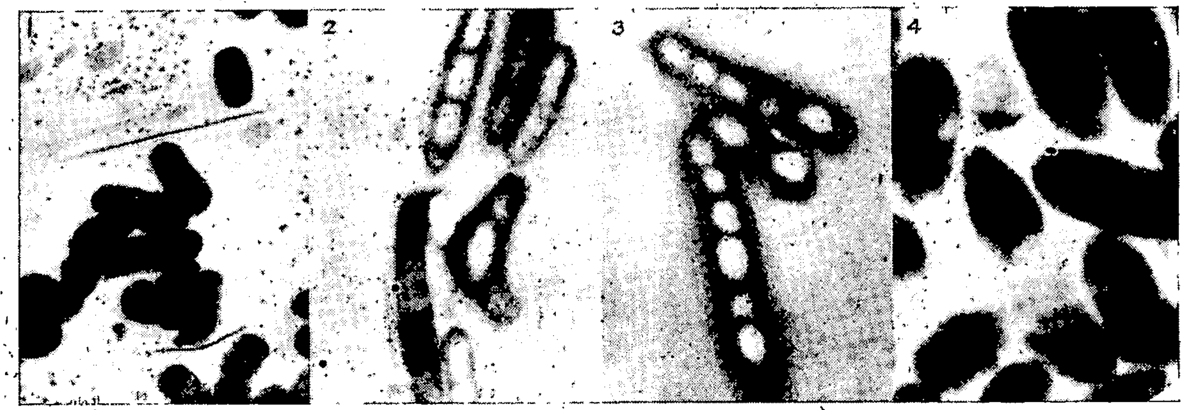

Fig. 1. INOCULUM OF AVIAN TUBERCLE BACILLI, FROM A CULTURE FOUR WEEKS OLD
Figs. 2 and 3. INTERMEDIATE FORMS AFTER 24 HOURS AND THREE DAYS INCUBATION ON LOEWENSTEIN MEDIUM
Fig. 4. FORMATION OF DAUGHTER RODS AFTER FOUR DAYS. × 15,000

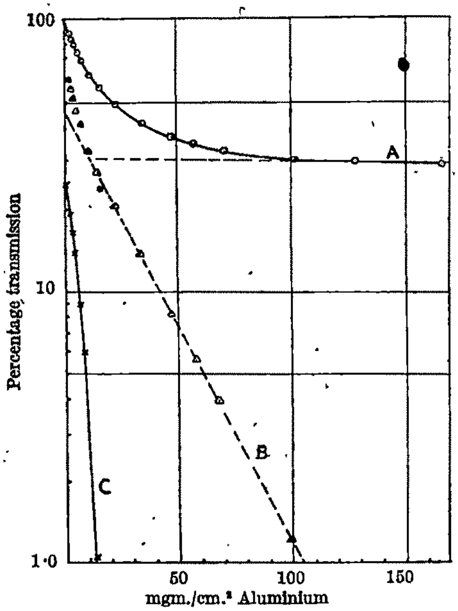

Fig. 1. ALUMINIUM ABSORPTION CURVE
A, *K* X-ray and γ-background ; *B*, *L* X-rays, half-thickness 17 mgm./cm.² ; *C*, electrons range ~ 11 mgm./cm.²

(2) Electromagnetic radiation of half-thickness 17 ± 1 mgm./cm.² aluminium, 124 ± 4 mgm./cm.² lead and 15 ± 0·4 gm./cm.² lead, corresponding respectively to energies of 8·7 keV., 59 keV. and 1·83 MeV. The lead absorption of the two harder components is shown in Fig. 2.

The ratio of electrons to quantum radiation was determined for an 'infinitely thin' sample mounted on a mica slip of mass thickness 0·6 mgm./cm.². Making corrections for counting fluctuations, for absorption in the counter window, air gap, etc., and assuming equal counting efficiencies of 1 per cent for the 59 keV. and 1·83 MeV. rays, with an efficiency of 3·3 per cent for the 8·7 keV. ray, the following ratios were obtained: Electrons : 8·7 keV. ray : 59 keV. ray : 1·83 MeV. ray = $2 \times 10^{-2} : 1{\cdot}0 \pm 0{\cdot}1 : 1{\cdot}0 : 1{\cdot}0 \pm 0{\cdot}2 \times 10^{-2}$.

The sample was further investigated using a crude β-ray spectrometer, measurements being made with fields up to 16,000 gauss/cm. No positrons or electrons of energy greater than 100 keV. were observed, but only a single peak of electrons. The peak value (Fig. 3) corresponds to an electron energy of 70 ± 2 keV.

The allocation of the isotope to mass 181, and the assumption that it is formed by a (*d*,2*n*) reaction in tantalum, seems reasonable. A single tungsten activity only, which has no tantalum daughter of half-life greater than a few minutes, has been found. The (*d*,2*n*) and (*d*,4*n*) reactions in tantalum only could lead to an active tungsten isotope, if the possibility of a long-lived isomer of stable W^{180} or W^{182} is excluded. The yield of the (*d*,4*n*) reaction with the 20 MeV. deuterons used would be too small by a very considerable factor to account for the observed activities. Further, no evidence of any isotope emitting X-rays was found in the separated tantalum fraction, which contained only the well-known 97-day Ta^{182}.

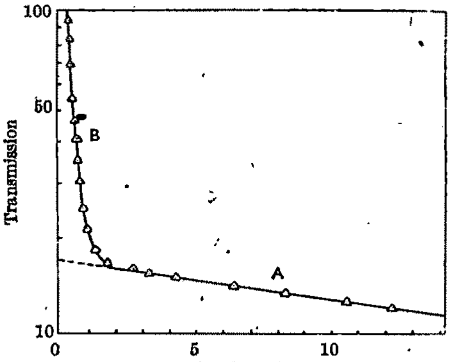

Fig. 2. LEAD ABSORPTION CURVE
A, γ-ray, 15 gm./cm.² half-thickness, measured up to 46 gm./cm.² lead ; *B*, *K* X-rays, half-thickness 124 mgm./cm.²

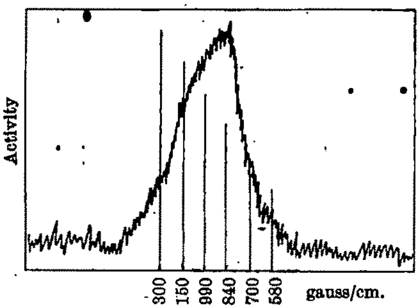

Fig. 3. ELECTRON DISTRIBUTION ON 'MAGNETIC COUNTER'

The measured half-thicknesses for the electromagnetic radiation agree well with the values of 17·8 mgm./cm.² aluminium, and 128 mgm./cm.² lead calculated for the *L* and *K* X-rays of tantalum respectively, using data given by Compton and Allison[1] for the energies and intensity ratios of tantalum X-radiation. The radiations of the new isotope are thus compatible with the assumption of orbital electron capture in tungsten. The small fraction of disintegrations through the 1·83 MeV. gamma-ray and conversion electrons might be accounted for by transitions to metastable states in Ta^{181}. De Benedetti and McGowan[2] have observed a metastable state in Ta^{181} of 22 microsec. half-life produced in the beta decay of Hf^{181}. The radiations[2,3] consist mainly of electrons of ~ 110 keV. energy, and it was suggested that these were due to conversion of a 180 keV. gamma-ray in the *K*-shell. The excitation energy of the metastable level would be ~ 180 keV., with a transition to the ground state involving a probable spin change of 3 units, from ½ to 7/2. The energy of the electrons observed in the decay of the new tungsten isotope agrees reasonably with that reported for the conversion electrons from Ta^{181*}, and corresponds to a 140 keV. gamma-ray completely converted in the *K*-shell. Since no 1·83 MeV. gamma-ray is reported in the disintegration of either Ta^{181*} or Hf^{181}, a further level above that of the 22 microsec. state must be assumed, with electron capture in W^{181} leading directly to each of the two states in approximately 1 per cent of the transitions.

Acknowledgment is due to Dr. T. G. Hamilton and the crew of the 60-in. cyclotron for assistance in bombardments, to Prof. G. T. Seaborg for his advice and criticism, and to the University of California for the use of its facilities.

Primary Ionization of β-Particles in Alcohol Vapour and Argon

THE efficiency of a counter for detecting ionizing particles can be written

$$\varepsilon = 1 - \exp(-Spl/76), \qquad (1)$$

where S is the primary ionization of the particle in the gas at N.T.P., p the pressure in cm. of the contained gas at 0° C., and l the length of the path of the particle in the counter. T. Graf[1] has made use of this fact to measure the primary ionization of β-particles in air. Two counters were placed in a spectrograph so that all particles passing through the second counter had, of necessity, also passed through the first. If N is the rate of counting in the second counter and N_c the coincidence counting-rate, the efficiency of the first counter is given by

$$\varepsilon = N_c/N. \qquad (2)$$

A knowledge of l and p then enables S to be calculated from equation (1).

We have, by this method, investigated the primary ionization of β-particles in mixtures of argon and ethyl alcohol vapour. For a mixture, formula (1) can be written

$$\varepsilon = 1 - \exp\{-(S_1p_1 + S_2p_2)l/76\}. \qquad (1a)$$

S_1 and S_2 can be evaluated by determining ε for two different combinations of the partial pressures p_1 and p_2.

The experiment was performed for β-particles of one energy only, namely, 0·42 MeV., and the mean values obtained were 79·0 ion pairs/cm. in alcohol vapour and 29·8 ion pairs/cm. in argon. These are consistent with values of 68·7 ion pairs/cm. and 25·9 ion pairs/cm. respectively for β-rays of energy 1 MeV.[2].

The value for argon is in agreement with measurements made with fast cosmic rays[3].

Hazen[4], by plotting a curve of primary ion pairs/cm. against electrons per molecule for five gases and extrapolating, estimates a value of 33 ion pairs/cm. for alcohol vapour. By adding the measured values for C_2, $3H_2$ and $\frac{1}{2}O_2$, he obtains a value of 42 ion pairs/cm. On either basis the value obtained is considerably smaller than the value we have measured. Indeed, on theoretical grounds[5] the measured value of 69 ion pairs/cm. is only consistent with an effective ionization potential of 7–8 electron volts.

It is noteworthy that the efficiency of a counter containing alcohol vapour at 1 cm. mercury pressure measured by Rochester and Jánossy[6] suggests a value of at least 61 ion pairs/cm. for alcohol vapour.

If any single ion pair escapes detection in the argon-alcohol counters, the value of the primary ionization for alcohol vapour would be even greater than 69 ion pairs/cm. This type of counter is, however, likely to be 100 per cent efficient, in contrast with the slow types used in earlier work[1,7,8].

Relations Between Structure-Factors

IF the edges of the unit cell of a crystal are all taken equal to 1, the electron-density function can be expressed as a three-dimensional Fourier series of the form

$$\rho(x,y,z) = \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F_{h,k,l} \exp\{2\pi i(hx+ky+lz)\}.$$

It is a commonplace of crystallography that X-ray diffraction methods can tell us the value of $|F_{h,k,l}|$ but never the actual phase of $F_{h,k,l}$. If we restrict ourselves to the case of a centro-symmetric crystal, we can take the F's real and so

$$F_{h,k,l} = \alpha_{h,k,l}\,|F_{h,k,l}|,$$

where the second factor on the right-hand side is known and $\alpha_{h,k,l} = \pm 1$.

Harker and Kasper[1] have recently shown that the $F_{h,k,l}$'s must satisfy certain relations of inequality, and that these relations sometimes enable one to decide unequivocally for some values of (h,k,l) whether $\alpha_{h,k,l}$ is $+1$ or -1. I have succeeded in extending these ideas and have established several large classes of inequalities between $F_{h,k,l}$'s. Applying the inequalities to the data on oxalic acid given by Robertson and Woodward[2], I have been able to determine the signs of some forty-two terms. I believe that more of the signs can be obtained directly, though I have not yet succeeded in doing so. In any event, however, these forty-two terms give a more than adequate first approximation, which can be followed up either by the usual methods or by the use of modern computing machinery.

Apart from the practical application of these ideas to the determination of phases, they also lead to some rather curious restrictions on the structure-factors. I have investigated a number of cases and have verified that these restrictions were, in fact, always satisfied, though no really adequate physical explanation of them suggests itself.

A full account of the whole subject will shortly be published elsewhere.

Meson Decay and the Theory of Nuclear Forces

IN recent observations with the photographic plate method, Lattes, Muirhead, Occhialini and Powell[1] have given direct evidence of cosmic ray mesons with two different masses; furthermore, in some of their pictures the heavier meson stops in the emulsion and emits a lighter meson. At first one is tempted to identify these two mesons with the vector and pseudoscalar ones postulated in the Schwinger mixed meson theory of nuclear forces. Wentzel[2] has, in fact, recently suggested that a vector meson can disintegrate into a pseudoscalar meson plus a photon, and one might conjecture whether this is not the process observed by the Bristol group[1]. According to calculations by Finkelstein[3], this process has a lifetime of 4×10^{-18} sec. and would thus be too fast to be detected in the plate. Finkelstein's results show, in addition, that the contribution of the vector meson instability to the soft component of cosmic radiation would result from that process, that is, from photons and not from β-decay, which would then be slower by a factor of 10^{10}.

More recent data[4] indicate, however, that the meson decay of mesons is probably accompanied by the ejection of light neutral mesons instead of photons. If this is true, Schwinger's usual mixed theory cannot account for the meson decay. Apart from the difficulty that Finkelstein's theory gives too short a life-time for this process, one would have to assume in this theory, besides the usual vector and pseudoscalar mesons, lighter mesons with spin 1. The scheme of the process would then be

$$\mu_v^{\pm} \rightarrow \mu_{ps}^{\pm} + \mu'_0, \qquad (1)$$

where μ'_0 is a spin 1 neutretto with a mass of the order $\frac{1}{2}$ of that of $\mu_v^{\pm}$ [4]. The additional assumption of a light vector neutretto field to account for this scheme would destroy the regularity of the non-relativistic potential of two nucleons in Schwinger's theory, unless a corresponding light pseudoscalar neutretto field were also introduced. One possibility which is open is given by a non-symmetrical mixture of two meson fields. Hulthén has already suggested a mixture of a neutral scalar and a charged pseudoscalar field[5]. But one might assume that for a given field the meson mass and the coupling constants depend on the charge. In this case, the potential energy of two nucleons as derived from a vector field would be

$$V = \sum_a \tau_a{}^{\mathrm{I}} \tau_a{}^{\mathrm{II}} \left\{ (g_1{}^a)^2 + \tfrac{2}{3} (g_2{}^a)^2 (\vec{\sigma}_{\mathrm{I}} \cdot \vec{\sigma}_{\mathrm{II}}) - \tfrac{1}{3} (g_2{}^a)^2 S \left(\frac{3}{(\mu_v{}^a r)^2} + \frac{3}{\mu_v{}^a r} + 1 \right) \right\} \frac{\exp\,(-\mu_v{}^a r)}{r};$$

$$S = \text{tensor force};$$

and analogously for the potential as deduced from the pseudoscalar field. One can then have immediately the potential by mixing the two fields.

We have, in particular, examined the non-symmetrical Møller – Rosenfeld mixture[6]. In this case, and assuming that the coupling constants are the same for charged and neutral mesons, the theory will give a neutron-proton interaction in the ^1S state slightly larger than the (specifically nuclear) proton-proton interaction in the same state if the neutral meson mass is slightly larger than the mass of charged mesons. Such a result might be consistent with Hanstein's observations[7]. In Born's approximation, the effect of varying the neutral meson mass on the anisotropy of neutron-proton scattering at 14 MeV. gives no substantial deviation from the prediction of the symmetrical theory. However, one would need a neutral meson lighter than the charged ones for process (1), and this would make the proton-proton potential in the singlet state larger than the neutron-proton potential in the same state, which is at variance with the available experimental evidence. The same conclusions are expected to result in the case of a non-symmetrical Schwinger's mixture.

Another possibility would be to assume light pseudovector mesons in addition to pseudoscalar and vector mesons. But there still remains the difficulty of too short a life-time for the meson decay with emission of photons, if one wishes to identify the heavier meson[1] of the Bristol group with a spin 1 meson. If, therefore, the meson decay of mesons is accompanied by the emission of light neutrettos, a more radical change will be needed in the present meson field theory of nuclear forces.

Interpretation of Radio Echoes from Polar Auroras

IN a recent communication, Lovell, Clegg and Ellyett[1] describe radio echoes from polar auroras. A remarkable feature was a persistent echo on 6·5 metres wave-length (46 Mc./s.) with an amplitude three times the noise-level and a distance of 480 km. The echo was not observed on 4 metres wave-length; it finally disappeared when striations occurred in the aurora.

The observers have kindly supplied the following data on the radar set used for the observations: peak transmitter power 50 kW. on 6·5 m., 100 kW. on 4 m.; aerial gain of 4 compared with a free dipole for transmitter and receiver on both wave-lengths; noise-level equivalent to $1 \cdot 8 \times 10^{-14}$ watts receiver input on 6·5 m., and to $0 \cdot 4 \times 10^{-14}$ watts on 4 m.

If the echo was due to reflexion from a plane surface, the reflexion coefficient, that is, the ratio between incident and reflected energy, would be of the order 5×10^{-7}. The well-defined range of the echo indicates that reflexion from a plane surface is a plausible assumption, and even if the plane reflector is replaced by an irregular surface, the magnitude of the reflexion coefficient would not be substantially altered, since the aurora covered an appreciable area of the sky.

Radar observations of meteors during this auroral display indicated no increase in the absorption up to 90 km. height, and the electron collision frequency at greater heights is too small to be effective at radio frequencies of 46 Mc./s. or more. The very low reflexion coefficient is therefore not due to absorption, but indicates that the auroras were practically transparent to radio waves of 46 Mc./s. frequency. *The electron density must therefore be considerably smaller than* $2 \cdot 6 \times 10^7$ *electrons per c.c.*

In a transparent layer of uniform electron density, the reflexion coefficient depends on the electron density and on the sharpness of the boundary layers. For a given maximum electron density, the reflexion coefficient is highest when both boundaries are perfectly sharp, and the radiation from both boundaries is received with the same phase. If these conditions are fulfilled, the optimum reflexion coefficient is

$$R = \frac{e^4}{4\pi^2 m^2 \nu^4} N_0{}^2. \qquad (1)$$

Equation (1), which is valid for small R, shows that if $R = 5 \times 10^{-7}$, *the electron density* N_0 *must be greater than* 4×10^4 *electrons per c.c.*

If the boundaries are diffuse, the optimum reflexion coefficient R is reduced by a factor

$$f = \left| \frac{1}{N_0} \int \frac{dN}{dx} \exp\left(i \frac{4\pi}{\lambda} x\right) dx \right|^2. \quad (2)$$

It is assumed in (2) that R is considerably less than unity. λ is the radio wave-length *in vacuo*; the integration is extended over the boundary layer.

If N_0 is near the lower limit, f must be nearly unity; if N_0 is approaching the upper limit, f must be of the order 10^{-6}. From these limiting values of f we can obtain information on the sharpness of the boundary layers. Assume, for analytical simplicity, that

$$\frac{dN}{dx} = \frac{N_0}{a\sqrt{\pi}} \exp\left(-\frac{x^2}{a^2}\right), \quad (3)$$

which would correspond to a sharp boundary which has been subject to a diffusion process. We find in this case

$$f = \exp\left(-\frac{8\pi^2 a^2}{\lambda^2}\right), \quad (4)$$

and using the lowest permissible value of f, we find that $a < 3$ metres.

It is known from aurora photographs[2] that the sides of draperies and rays appear sharp to within less than a few hundred metres; the limit is set by the resolving power of the cameras and films. From the present interpretation of radio echoes, it appears that the boundaries are sharp within some metres. This conclusion depends to some extent on the analytical expression which is chosen to represent the electron distribution in the boundary layers, but different expressions give the same order of magnitude.

Diffusion in the aurora-levels is too fast for the boundaries of an accumulation of electrons to remain so sharp for 20 min. Aurora photographs show that the lower borders of arcs, draperies and rays are much less clean-cut than their vertical sides. For these reasons it is difficult to understand how the radio echo described by Lovell, Clegg and Ellyett could be caused by reflexion from the bright area which was observed near zenith. As an alternative interpretation it may be suggested that the echo was due to reflexion from the vertical surfaces of a stationary discharge (an auroral arc) at a range of 480 km. close to the northern horizon, and that the reflexion occurred from the point where the radius from the radar station was normal to the surface of the arc. Since such arcs follow the lines of magnetic field, this point would be located at about 200 km. height over the north of Scotland; aurora records from this region during the night of August 15–16 would be very desirable. It is worth noting that a height of 200 km. is well above the region of maximum luminosity in ordinary auroral arcs.

As seen from equations (1) and (2), the reflexion coefficient should decrease with decreasing wave-length, and it may be readily understood that the echo was observed on 6·5 metres, but not on 4 metres wave-length. The disappearance of the echo when the aurora split into rays is also to be expected, since a plane arc is a more efficient reflector than a cylindrical ray.

Further observations of this kind during magnetic storms and auroras would be desirable. If the echoes detected by Lovell, Clegg and Ellyett are due to reflexions from a point well above the luminous parts of an auroral arc, there is a possibility that echoes might be observed from the current sheets outside the earth's atmosphere during magnetic storms. For this purpose one might, as a first guide, assume that the auroral discharges take place on the surface generated by the magnetic field lines through the aurora zone, and for each locality the most favourable directions and ranges can be readily evaluated from the condition that the radius from the station should coincide with the normal to this surface.

Low-Temperature Polymerization of Isobutene by Titanium Chloride

It has been shown in previous communications[1,2] that the low-temperature polymerization of isobutene in hexane solution by titanium chloride ($TiCl_4$) requires a co-catalyst. Water was found to be an effective co-catalyst, but only when introduced into the reaction mixture in the form of vapour, where it presumably forms crystallites of high specific surface which react with the titanium chloride. These considerations, and the milky appearance of the polymer solution at the end of the reaction, indicated that the initiation step at least might be heterogeneous.

Using the apparatus and method previously described[2], it was found that the reaction could also be initiated by the addition of a few drops of commercial concentrated sulphuric acid. 20 per cent oleum had the same effect, so that it is improbable that the active principle in the sulphuric acid was the water contained therein. Neither sulphuric acid nor oleum alone (without titanium chloride) initiate polymerization at −70° to −80° C., although they do so at room temperature. The reaction initiated at about −80° C. by concentrated sulphuric acid or oleum as co-catalyst is of an extreme violence comparable with that of the boron trifluoride catalysed reaction.

Concentrated sulphuric acid, oleum and water were not considered altogether suitable co-catalysts for kinetic studies, and a co-catalyst was sought which would be soluble and which would form a titanium chloride complex also soluble in hexane. The substances acting as co-catalysts in the boron trifluoride catalysed, room-temperature, gas-phase polymerization of isobutene, such as acetic acid[3,4,5], which are soluble in hexane, were found to act as inhibitors to the titanium chloride catalysed, low-temperature, liquid-phase polymerization of isobutene. Further search was made for a hexane-soluble acid of strength comparable to sulphuric acid. It was found that dry trichloracetic acid in hexane solution was an efficient co-catalyst. The titanium chloride – trichloracetic acid complex was found to be soluble in hexane at the concentrations used at temperatures so low as −85° C. Polymer solutions produced by titanium chloride – trichloracetic acid are free from opacity or even opalescence until exposed to the atmosphere. With a ratio of chloride to acid less than about 4, the curves showing the progress of reaction with time are slightly sigmoid, but for higher values of this ratio their slopes decrease monotonically from the start. For starting temperatures near −80° C., the maximum rate of the polymerization under adiabatic conditions is found to be a function of the concentrations of isobutene, titanium chloride and trichloracetic acid, and of the initial temperature. The detailed relationships are being investigated.

Picric acid, the dissociation constant of which is of the same order as that of trichloracetic acid, was found to be inactive as co-catalyst, but did not affect the polymerization afterwards induced in the same reaction mixture by the addition of trichloracetic acid. Monochloracetic and dichloracetic acids were found to possess practically no co-catalytic activity at −75° C., but slowed down considerably the polymerization afterwards induced by the addition of trichloracetic acid.

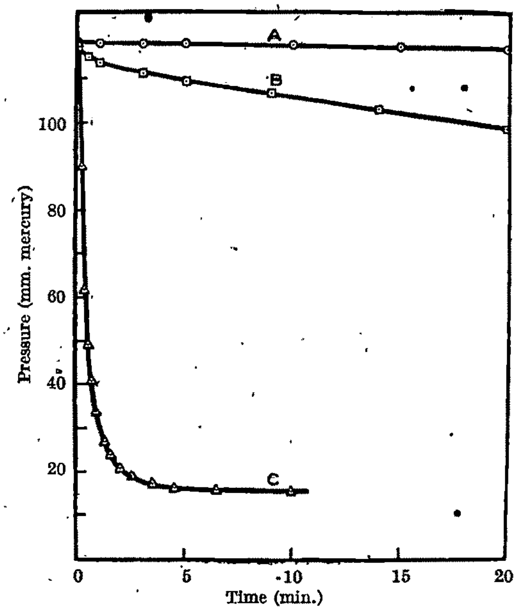
Polymerization of Olefins by Friedel-Crafts Catalysts

Earlier work has shown that pure isobutene gas and pure di-isobutene vapour do not undergo reaction when mixed with gaseous boron trifluoride[1]. In the presence of a trace of some third component, or co-catalyst as we shall call it, these monomers undergo very rapid polymerization when mixed with boron trifluoride. Water[1] and *t*-butyl alcohol[2] act as co-catalysts in this way.

We now find that acetic acid also is an effective co-catalyst in these reactions. Isobutene gas containing as little as 0·06 per cent acetic acid vapour polymerizes very rapidly when boron trifluoride is mixed with it (Curve *C*). The introduction of boron trifluoride into this isobutene – acetic acid mixture is accompanied by a dense fog and by the formation of liquid polymer throughout the whole system. The slow reaction which occurs when purified isobutene gas is mixed with boron trifluoride is shown for comparison (Curve *A*).

The action of the co-catalyst has been attributed to the fact that it forms an addition complex with the boron trifluoride, which complex then loses a proton to the olefin, thus forming a carbonium ion which can initiate a polymerization chain[2].

We have prepared a crystalline boron trifluoride acetic acid complex by mixing acetic acid vapour with excess boron trifluoride gas*. The introduction of purified isobutene gas into a system containing crystals of this complex resulted in the rapid polymerization of the isobutene. This polymerization took place entirely on the surface of the complex. Since the complex covered only a very small portion of the reaction vessel surface, the major part of this surface was completely free from liquid polymer.



A : Boron trifluoride + purified isobutene
B : „ „ „ „ + 0·01 mm. acetic acid
C : „ „ „ „ + 0·06 „ „ „

This experiment shows that in this case the polymerization of isobutene is a heterogeneous process occurring on the surface of particles of complex.

Further evidence for this conclusion was obtained by the following method. Isobutene gas, containing sufficient water as co-catalyst to give a slow reaction, was mixed with boron trifluoride in a reaction vessel (vessel 1). After 1–2 hours, this reaction mixture was expanded into a second reaction vessel (vessel 2), and the connexion between these vessels was then closed. It was found that the polymerization continued in vessel 1, but that there was no reaction in vessel 2.

Use of a Palladium Tube Technique in the Study of the Role of Hydrogen in Combustion Systems

From the experiments of H. B. Dixon[1] and later workers, the importance of the presence of hydrogen-containing species in the combustion of carbon monoxide is generally recognized. The wet oxidation is a chain reaction in which these bodies provide the chain carriers. Recent experiments[2,3] which prove the dominant role of the wet carbon monoxide–oxygen reaction during the high-temperature oxidation of carbon leads to a similar conclusion, namely, that small amounts of hydrogen or its compounds are necessary for the production of fully burnt gases during the combustion of solid fuels.

We have found that the stationary hydrogen concentration obtaining during the combustion of carbon

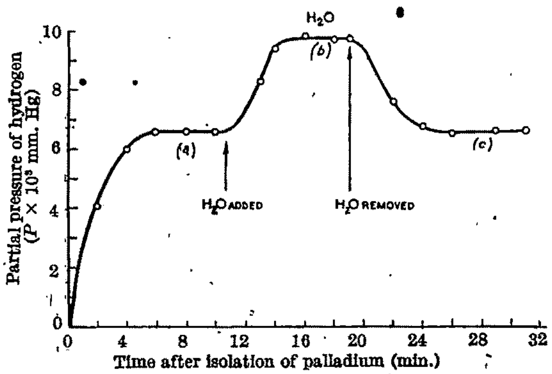

Fig. 1

monoxide – air mixtures at a jet flame may be conveniently followed by inserting an evacuated thin-walled palladium tube in the flame and observing the equilibrium pressure (due to hydrogen) set up within it[4].

In our experiments the gases were dried over magnesium perchlorate, and contained sufficient moisture to give a steady flame even when small amounts of inhibitors were present in the air. The balance of heat transferred from the flame to the palladium tube and heat lost by conduction and radiation was such as to maintain the tube at a temperature near 700° C.

We found that: (i) an equilibrium pressure was reached in 6–8 min. (Fig. 1 at *a*); (ii) the pressure within the tube responded rapidly when moisture was added to the gases fed to the flame (Fig. 1 at *b*); (iii) the diffusion process was quantitatively reversible and hence quite specific for hydrogen at the above temperatures. Fig. 1 shows at *c* that the pressure set up in the palladium tube due to addition of water vapour to the gases falls to its initial value when the water is cut off.

The equilibrium state is presumably a property of the flame alone. The approach to that state is a property of the flame, the tube, and the volume of the evacuated space. Since the reaction $H_2 \rightleftharpoons 2H$ occurs at the palladium surface, it is presumed that the measured pressure is due to the average total hydrogen concentration of the flame in contact with the palladium.

The effects of inhibitors of the combustion on the hydrogen pressure may be conveniently followed. Fig. 2 shows the influence of a minute quantity of phosphorus trichloride on the measured pressure; hydrogen chloride gives a similar result. A correlation is possible between the hydrogen content of the flame and its stability (that is, the flame speed) in the presence of the added compounds. In this connexion, it is interesting to observe that Tanford and Pease[5] have recently made estimates of the hydroxyl and atomic hydrogen and oxygen concentrations in carbon monoxide flames. They find a striking correlation between burning velocity and atomic hydrogen concentration, but little correlation with hydroxyl and atomic oxygen concentrations.

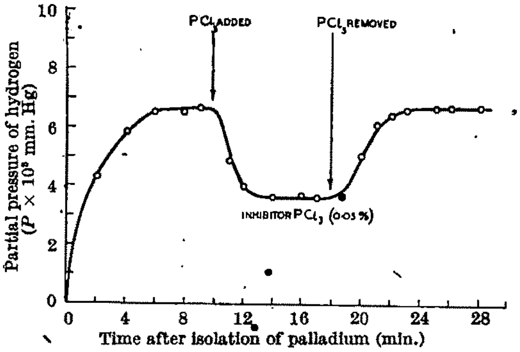

Fig. 2

It is found quite generally that those compounds which markedly increase the ratio of carbon monoxide to dioxide in the combustion of carbon[6] at 750–850° C. drastically reduce the hydrogen content of a carbon monoxide flame.

The technique is being used to investigate the effect of fine powders on combustion processes in gaseous and solid fuel systems, as part of a programme relating to the control of reactions in fuel beds. The results will be reported fully elsewhere.

Nature of the Hydrogen Bond in Potassium Hydrogen Fluoride

IN 1941 Ketelaar[1] published accurate measurements on the infra-red absorption and reflexion spectra of potassium hydrogen fluoride (KHF_2). The two strong peaks of 1450 and 1222 cm.$^{-1}$ were interpreted as a doubling of the fundamental asymmetric valence frequency ν_3 belonging to the vibration of a proton between two F^- ions. The doubling was assumed to be caused by a double-minimum potential curve of the type occurring in the NH_3 molecule. The splitting of the lowest vibrational level was estimated to be 25 cm.$^{-1}$ and the distance between the two equilibrium positions 0·70 A.

On the basis of this interpretation of the spectrum one would expect, however, that the ratio of the distances between the two absorption peaks for KDF_2 and KHF_2 should be very much smaller than the value (about $2^{-1/2}$) which was found experimentally. This can be deduced from the formulæ of Dennison and Uhlenbeck[2], and is due to the fact that in KDF_2 the mass of the resonating particle is twice as large as in KHF_2. It can scarcely be expected that the change in the potential curve accompanying the substitution of H by D would compensate this effect almost exactly. Therefore, we believe that Ketelaar's interpretation of the spectra is not conclusive.

There is another criterion which may be used in order to test Ketelaar's assumption. This assumption leads to the conclusion that the dielectric permittivity of KHF_2 should be strongly dependent on temperature. This is a direct consequence of Van Vleck's principle of spectroscopic stability[3], which predicts a term proportional to T^{-1} contributing to the permittivity at temperatures large in comparison with the double minimum splitting of the lowest level; that is, the dielectric behaviour at these temperatures should be exactly as if free permanent electric dipoles were present in the crystal.

In order to test this point, Dr. Gevers and Mr. Camfferman of this Laboratory carried out some dielectric measurements on potassium hydrogen fluoride in 1945. They found that the temperature coefficient $\varepsilon^{-1}\, d\varepsilon/dT$ of the dielectric permittivity was about $+ 2 \times 10^{-4}$ in the temperature region between 80° and 300° K., while the loss angle was smaller than 10^{-3}. From Ketelaar's data one would expect a negative temperature coefficient of an order of magnitude varying from $- 10^{-2}$ to $- 10^{-3}$ in this temperature region.

We are thus in agreement with the conclusions of Pitzer and Westrum[4], who based their arguments on the absence of a heat-capacity peak in the low-temperature region.

Reaction of Hydrogen Atoms with Solid Carbon

Avramenko[1] has recently announced the discovery of evidence for the direct reaction of atomic hydrogen with soot at a temperature of 100° C. We wish to report additional confirmation of the occurrence of this reaction in independent work which has been proceeding in our laboratory for several months.

Hydrogen atoms, produced by the standard Wood–Bonhoeffer technique[2], were pumped into a cylindrical reaction chamber of approximately 7 cm. diameter and 35 cm. length, the walls of which were internally 'poisoned' against excessive hydrogen-atom recombination by means of a coating of phosphoric acid. At an operating pressure of 0·4 mm., a 20 per cent atom concentration was readily maintained in the reactor, into the centre of which could be introduced a water-cooled glass finger thinly covered with solid reactant. Provision was made for collecting volatile products other than hydrogen by including in the exhaust system a silica gel-filled trap maintained at liquid air temperature. This method has been successfully utilized in work of this nature by several previous experimenters[3], and blank runs with hydrogen – methane mixtures in our present apparatus confirmed the suitability of the procedure. Possible higher hydrocarbons would, of course, be retained even more strongly than methane.

Runs of 45 minutes duration were carried out, in which soot deposits (made by 'smoking' the glass finger with a gas flame) were treated with hydrogen atoms. Light deposits were observed to disappear completely within a few minutes, although heavier coatings were cleaned off only partially during the reaction period. In some of the runs with heavy carbon deposits, the gaseous product exclusive of hydrogen was collected in the manner already described, and separated in part by distillation at − 185° and at − 100° C. Typical results, given in terms of c.c. of gaseous product measured at N.T.P. were as follows:

c.c. product volatile at − 185° C. (i.e., CH_4)	c.c. product volatile at − 100° C. (i.e., C_2 to C_5 fraction)	c.c. product involatile at − 100° C.	Temp. of cooling water in glass finger
6·0	0·5	nil	(uncooled)*
6·3	0·9	nil	45° C.

* No cooling water passed in this run. Temperature of sooted finger probably high, due to heat of hydrogen-atom recombination.

The experiments thus far have been of a purely exploratory nature, and a more comprehensive investigation is now in progress. The mechanism of the reaction poses an interesting kinetic problem, particularly with respect to the identity of such free organic radicals as may appear in the gas phase.

Effect of Injection of Adrenaline on the Anaerobic Glycolysis of Rat Diaphragm

Part of the action of adrenaline in raising the blood sugar has been attributed by Cori *et al.*[1] to a decrease in utilization of glucose by the tissues. Other workers arrived at different conclusions.

For the following experiments, the anaerobic glycolysis of rat diaphragm was determined 40–60 min. after subcutaneous injection of 1 mgm. adrenaline/kgm., on the assumption that the rate of glycolysis would reflect glucose consumption in the skeletal muscle throughout the body. The Q_{CO_2} for diaphragm of adrenaline-injected animals was found to be 29 per cent inhibited as compared with controls (see table).

Rats	Average Q_{CO_2}		Inhibition (per cent)
	Untreated controls	Adrenaline treated	
Normal* (36 expts.)	2·44	1·74	29
Adrenalectomized (12 expts.)	3·38	2·30	31
Hypophysectomized (26 expts.)	2·38	2·32	0

* For every experiment two rats were used.

The failure to obtain any inhibition of glycolysis by addition of adrenaline to diaphragm or muscle extracts *in vitro* suggested an indirect action. Such an indirect action could consist in a stimulation by adrenaline of the hypophysis or the adrenal cortex, causing a release of the corresponding hormones leading to the suppression of carbohydrate utilization. A possible mechanism for this action could be the hexokinase-inhibiting effect of the hypophysis described by Colowick *et al.*[2], which effect is increased by adrenal cortical hormone and reversed by insulin.

Addition of diabetogenic hypophysis extract kindly made available by Prof. E. G. Young did not affect diaphragm glycolysis. Adrenal cortical hormone (eschatin), however, gave in nearly all cases an inhibition of 30–50 per cent. Insulin addition caused an increase in glycolysis. Since the intrinsic pituitary hormone content of the diaphragm may be optimal and since added hypophysis extract may not penetrate, these results are not in disagreement with Colowick's theory.

Next the effect of adrenaline injection was studied on the diaphragm glycolysis of hypophysectomized and of adrenalectomized animals (see table).

Adrenalectomized animals show a normal response to adrenaline injection, indicating that indirect stimulation of the adrenal cortex by adrenaline as described by M. Vogt[3] plays no part in the effect. Hypophysectomy, however, abolishes the adrenaline effect. The part played by the hypophysis could be a release of a hexokinase-inhibiting hormone under the influence of injected adrenaline, but other mechanisms, in particular pituitary influence on the action of adrenaline itself, or an active derivative, remains possible. Investigations to elucidate these possibilities are in progress, and a detailed report will be published later.

Influence of Adenohypophysectomy on the Transfer of Salt Across the Frog Skin

IT is well known that the isolated skin of the frog is able to transport salt from its outside to the inside when bathed with frog Ringer on both sides[1]. In view of the fact that cortical hormones play an important part in the reabsorption of sodium chloride in the kidney, an investigation was made to learn whether the skin of hypophysectomized frogs, in which cortical secretion presumably is considerably decreased, is still able actively to transport salt. In specimens of *Rana temporaria* the adenohypophysis was removed, and the animals, together with unoperated controls, were kept without food in water at 10°–15° C. Three operated animals, two males and one female, of healthy appearance, were used in the experiments. The operations were carried out in November. The secretion of the skin of the operated frogs was very markedly reduced. This effect of hypophysectomy on the toad has already been described by Aubrun[2].

In May—about six months after the operation—the skin was tested (1) for ability to transport salt, and (2) for permeability to salt. Pouches made from the skin of the thigh (cf. Huf) were filled with 1·5–2 ml. frog Ringer or water and placed in small vessels containing 10 ml. aerated frog Ringer. The *p*H was kept at about 7·4, the temperature at 22° C. The passage of salt through the skin was followed either by chloride titration (when Ringer was used inside the pouch), or by conductivity measurements on the content of the pouches (when starting with water inside the pouches) using a Philip's Philoscop, A.C. 1,000 cycles[3]. Table 1 shows the result of the experiments when Ringer was applied on both sides of the skin. As was to be expected, the transfer of salt occurred from the physiological outside to the physiological inside of the skin. The results are expressed in μ mol. Cl per hour per cm.[2] of the skin. It is seen that with regard to the ability of transporting salt, no demonstrable difference exists between the skin of normal and of operated animals. Starting with water inside the skin pouch, the results given in Table 2 were obtained. The figures represent the rate at which salt was lost into the pouch. The skin of operated frogs is found to be several times more permeable than normal skin. It is therefore not surprising that the adenohypophysectomized frogs were unable to keep the chloride ion concentration of the blood at a normal level. Table 3 shows the chloride concentration in the lymph two and five months after the operation. The chloride determinations were performed on 3 mm.[3] samples of lymph taken from the lymph-sac by means of a Carlsberg constriction pipette through a small incision in the skin.

TABLE 1

	Hypophysectomized	Normal
μ mol. Cl/hr./cm.²	0·27, 0·37	0·24
	0·49	0·38
	0·56	0·54

TABLE 2

	Hypophysectomized	Normal
μ mol. Cl/hr./cm.²	0·73	0·05
	0·74	0·10
	0·82	0·13

TABLE 3

	Hypophysectomized		Normal	
	Months after operation			
	2	5	2	5
mmol./l. Cl of lymph	58	47	69	84
	64	55	75	75
	—	48	70	81

It may be concluded that the salt transport of the skin of the frog may function even in the absence of the adenohypophysis. However, directly or indirectly, perhaps via cortical action, this gland is necessary for the maintenance of the very low salt permeability characteristic of the normal skin.

Critical Moisture Content of Dehydrated Stockfish

INVESTIGATIONS conducted in this Laboratory into the dehydration of stockfish (*Merluccius capensis*) have indicated that the moisture content of the dried product has a great influence on its keeping quality.

Whereas such products as dehydrated vegetables, dried fruit, dried whole milk and dried eggs have their storage life lengthened with reduction of the moisture content of the dried product, the reverse relationship has been found to hold for dehydrated stockfish.

Below 8 per cent moisture content, there is a sharp reduction in the storage life of dehydrated stockfish with every decrement in moisture content. The deterioration takes the form of both discoloration and loss of flavour. The re-incorporation of the liquid extracted from the flesh during the preliminary cooking of the flesh by steam also retards the rate of deterioration, but not sufficiently to give an effective storage life. With increasing moisture content above 8 per cent there is still evident a small improvement in quality of the dried product up to the moisture limit where spoilage by micro-organisms intervenes. The improvement per increment of moisture content is small above 16 per cent moisture content.

The storage life of the dehydrated product packed in an inert atmosphere with moisture content less than 5 per cent is approximately six weeks, and with a moisture content of 16 per cent it is up to twelve months.

The reversal of the relationship that exists between moisture and deterioration in other dehydrated products is of considerable interest in view of the fact that many laboratories are searching for clues as to the nature of the deterioration that takes place in dehydrated products.

Cobalt Deficiency in Sligo

ON a farm on sandy soil in Co. Sligo where sheep pine and die, and cattle show pronounced ill-health, the administration of cobalt to the stock restores health and increases productivity to a remarkable degree. The herbage is definitely deficient in cobalt. The stock on this particular farm are confined to it, while the stock from neighbouring farms in which the pronounced cobalt deficiency symptoms do not appear have alternative pastures.

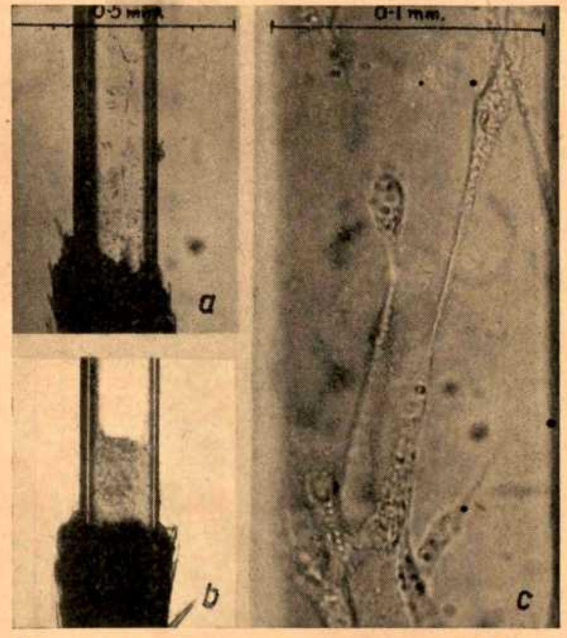
A Method for Observing Growing Epithelial Tissue in *Rhodnius prolixus* (Hemiptera)

ALTHOUGH it has been accomplished in the case of the hæmatocytes and imaginal disks of *Drosophila*[1], the cultivation of insect tissue *in vitro* has proved to be very difficult. A method by which growing epithelial tissue can be observed in transmitted light, while still in connexion with the hæmolymph and the epithelium of the living insect, may therefore be of general interest. The method is based on the fact that epithelial cells, after injury, will grow along any surface, and that if a wound is covered with glass, the cells will spread rapidly on the surface of the glass[2].

A hind leg of a freshly fed fifth-stage nymph of *Rhodnius* is amputated in the distal part of the tibia. A fine glass tube about 2 mm. long and 0·15 mm. thick is then introduced into the opening of the tibia, so that it is covered for about 0·2 mm. of its length by the cuticle. This operation is made while the leg is immersed in Ringer solution. The Ringer solution is then withdrawn and the distal end of the capillary tube sealed with paraffin wax. For the observation the insect is fixed on a special slide. The treated leg is immersed in water and covered with a cover-slip. For observing with the oil-immersion objective, the leg is imbedded in paraffin wax of low melting point up to the amputation level and the glass tube immersed in golden syrup. By this means excellent optical definition of the cells growing on the upper surface of the tube can be secured. At a temperature of 25° C. this preparation can be kept under quite normal physiological conditions for about twenty-five days, that is, until the insect moults. It is very sensitive to heat and to strong illumination.



PHOTOMICROGRAPHS OF CULTURES OF LIVING EPITHELIAL TISSUE IN *Rhodnius prolixus*. (*a*) EARLY STAGE (TWO DAYS) WITH HÆMATOCYTES AND FEW EPITHELIAL CELLS. (*b*) LATE STAGE (NINE DAYS) WITH CONTINUOUS EPITHELIUM. (*c*) SOME EPITHELIAL CELLS FOUR DAYS AFTER THE OPERATION

In a fresh preparation a great number of hæmatocytes can be observed. They are spherical or elongated while floating freely in the hæmolymph, but become more elongated and flattened when they attach themselves to the walls of the glass tube. Many cell divisions can be observed in hæmatocytes in the first days, but after five to six days they become vacuolated and degenerate very quickly, leaving behind little droplets.

After the first 12–14 hours the first epithelial cells migrate into the visible part of the tube. They are closely applied to the wall of the tube and move by extending and withdrawing pseudopodia. They are always connected with each other and with the epithelium of the leg by long, highly birefringent protoplasmic threads. The cells move at a speed of 30–40 μ per hour, so that after another twenty-four hours they may cover almost 1 mm. of the tube with a sparse network of cells, interconnected by protoplasmic processes. The movements of the single cells can easily be followed and many details observed. The addition of a green filter increases the visibility of the nucleus. Although at first the cells move only along the walls, the protoplasmic threads connecting them can loosen themselves from the wall and run right across the lumen of the tube. Other cells can then migrate along these threads, so that after a time these paths often become densely crowded. After about seven days, many cells congregate at a distance of about 0·5 mm. from the amputation-level. The empty proximal regions then gradually become filled up with cells, but the more isolated cells in the distal part of the capillary begin to degenerate. A continuous epithelium which covers about 0·3–0·5 mm. of the tube will be formed by the tenth day, and after that only cell divisions occur. The preparation is then no longer suitable for the observation of single cells. Nevertheless, I hope that the method will be of use in investigating the laying down of the new cuticle of the regenerating leg.

Economic Control of the Relapsing Fever Tick in African Houses

The control of the relapsing fever tick, *Ornithodoros moubata* Murray, which is widespread and alarmingly abundant in many townships and labour camps in East Africa, has hitherto proved uneconomic, owing to the marked resistance of the species to the common insecticides, and the consequent heavy dosage required. I have recently had occasion to carry out trials on a practical scale with a number of 'Gammexane' formulations, and the results have been so promising that it was thought opportune to bring the details of a simple method of treatment to the notice of all who are interested in the control of ticks.

It is a matter of simple experiment to demonstrate the outstanding toxicity of hexachlorocyclohexane to *O. moubata*. Individuals subjected to the lightest dusting with a commercial dust containing 0·5 per cent of 'Gammexane' begin to lose their power to co-ordinate leg movements after 4–6 hours. They may lose up to 10 per cent of their body weight in twenty-four hours by excessive coxal secretion, by defæcation of milky fluid, and probably also by increased permeability of the tough integument. There is in many cases a darkening of colour, due to the diffusion of ingested hæmoglobin compounds from the gut to the body cavity. The ticks become immobile, except for feeble but persistent, and sometimes rhythmical, leg movements, after periods varying from twelve hours to five days, according to age, and mortalities of 80–100 per cent result after 8–10 days. In the case of adult ticks, and particularly of gravid females, individuals have shown leg movements up to two months after treatment, but any eggs laid have invariably failed to hatch. The parallel action of D.D.T. 5 per cent dust is slower and less effective, although mortalities of 50–80 per cent have been secured after more than twenty days.

In the field, the most economic treatment has proved to be the 0·5 per cent 'Gammexane' dust, applied directly to the floors and the first few inches of the walls of infested houses. Application is made with a simple shaker such as a cigarette tin of the circular type, at the rate of 3–4 lb. of dust per 1,000 sq. ft. of surface. The results are checked by a standard system of survey, in which a team of five 'boys' searches the floors to a depth of 1½ in. at random for five minutes. By this means, the infestation figures in a labour transit camp have been reduced from an average of 20 per unit sample to less than 0·2 over a period of nine months. There was evidence that re-treatment was required after this time, possibly owing to consistent re-infestation from transit labourers, who commonly carry the ticks in their bedding.

Since the cost of the material used, if prepared by the dilution of the commercial dust concentrate (2·5 per cent 'Gammexane') with a local diluent, of which the best appears to be a light diatomaceous earth ('Diatomite'), is in the region of 4·5*d.* per lb., this treatment should be well within economic bounds for large-scale application. These experiments have been extended to cover an entire township, consisting of approximately 1,200 houses, 50 per cent of which are infested with *Ornithodoros*, with consequent high incidence of relapsing fever. It may be some time before the effect on fever statistics can be assessed, but the relief from the ticks is already widely appreciated, and the treatment has been officially standardized in several departments in Tanganyika as an advance on any control method previously known.

I am indebted to the Director of Agricultural Production for permission to publish this note.

Geological Age: the Extreme Antiquity of Pegmatites from Manitoba

An inspection of the available data on geological ages determined by the lead method shows that in two areas the pegmatite ages appear to be considerably greater than those of any other Pre-Cambrian pegmatites so far determined. These two areas are located in northern Karelia and south-east Manitoba, Canada.

The geological age of pegmatites from northern Karelia is quite often held to be the greatest age so far determined. Several specimens of uraninite have been analysed[1] and the ages, which have been recalculated here with the aid of Wickman's graphs[2], are invariably nearly 1,800 × 10^6 years, which is the mean of all the determinations. Some specimens of monazite have also been analysed[1], and although the age of each specimen is about the same (average 2,100 × 10^6 years), it is somewhat higher than the uraninite age. From these data, the probable age of the pegmatites from northern Karelia is therefore about 1,800–2,100 × 10^6 years. Unfortunately, no isotope analyses of the lead in these specimens are known, and it has thus not been possible to compute ages according to Pb^{206}/U^{238}, Pb^{208}/Th^{232} and Pb^{207}/Pb^{206} ratios, which would provide valuable evidence in support of, or against, the above ages for the northern Karelian pegmatites.

Two specimens of uraninite and two of monazite from Manitoba pegmatites have also given high ages, which, recalculated as stated above, range from 1,700 to 2,000 × 10^6 years. Lead from one specimen of uraninite and one of monazite has been analysed on the mass spectrograph, and serious discrepancies have been found in the 'ages' of these specimens according to whether the ages are calculated by Pb^{206}/U^{238}, Pb^{208}/Th^{232} or Pb^{207}/Pb^{206} ratios. These ages, taken from Nier[3,4], are given in Table 1.

Table 1

No.	Mineral and source	Pb^{206}/U^{238} age	Pb^{208}/Th^{232} age	Pb^{207}/Pb^{206} age
1	Uraninite, Huron Claim, S.E. Manitoba	1570 × 10^6 yr.	1252 × 10^6 yr.	2200 × 10^6 yr.
2	Monazite, ,,	3180 ,,	1830 ,,	2570 ,,

Nier[4] has pointed out that the Pb^{207}/Pb^{206} ages are quite likely to be the most reliable, and the agreement between the Pb^{207}/Pb^{206} uraninite and monazite ages given above is reasonably good. Consequently, although serious discrepancies are apparent, the agreement between the Pb^{207}/Pb^{206} ages indicates quite strongly that the age of the pegmatites from south-east Manitoba is one of the greatest yet reported.

Age determinations using the strontium method support this evidence. (For age determinations calculated according to strontium – rubidium ratios, a value of 5·8 × 10^{10} years, determined by Eklund[5], has been used for the half-life period of Rb^{87}.)

First, Strassmann found approximately 2·6 per cent rubidium and 0·155 per cent strontium, more than 99·7 per cent of which was found to be radiogenic[7] in lepidolite from the Silver Leaf Mine, south-east Manitoba, whence the strontium age is calculated as 1,830 × 10^6 years. However, some strontium may have been lost during analytical manipulations, and may be as much as 10 per cent[8], in which case the strontium age would be 2,000 × 10^6 years.

Secondly, using a spectrochemical procedure described elsewhere[9], strontium ages of four different specimens of lepidolite from south-east Manitoba have been determined (Table 2).

TABLE 2

No.	Source	Strontium age
1	Falcon Island, Lake of the Woods, S.E. Manitoba	2200 × 10^6 yr.
2	Along the Winnipeg River, ,,	2300 ,,
3	Silver Leaf Mine, along Winnipeg River, ,,	2100 ,,
4	,, ,, ,, ,, ,, ,, ,,	2350 ,,

(Probable experimental error in each case about ± 15 per cent.)

These ages agree satisfactorily and are also in reasonable agreement with the other ages that have been discussed. It might be argued that as no isotope data on the strontium in these specimens are available, contamination by ordinary strontium is possible. This possibility cannot be overlooked, but the evidence against it is very considerable. First, available mass spectrographic analyses (seven in all)[10,11] have shown radiogenic strontium to predominate in lepidolite. Secondly, the ages of about twenty-five specimens of lepidolite from various localities and of different ages have been determined[12], and with few exceptions no contamination is apparent. These ages include those of Pre-Cambrian pegmatites from New Mexico, Colorado, South Dakota and Ontario, all of which are of the magnitude of approximately 1,000 × 10^6 years and are only about half the Manitoba age. Thirdly, two of the above specimens are from the same pegmatite (Silver Leaf Mine) from which the specimen containing more than 99·7 per cent radiogenic strontium was taken; and fourthly, had contamination been significant, it is highly unlikely that agreement so close as that shown in Table 2 could occur.

A consideration of the ages given in Table 2, as well as of others that have been discussed, seems to establish beyond reasonable doubt that the pegmatites from south-east Manitoba are of extreme antiquity, and that with the possible exception of the north Karelian pegmatites, which may be of about the same age, they represent the most ancient portion of the earth's crust, on which it has been possible to determine the geological age. An age of 2,100 × 10^6 years is considered reasonable for these pegmatites.

The granites from south-east Manitoba with which the pegmatites are associated are intrusive into an ancient complex, referred to by Wright[13] as the Rice Lake Series, which is composed of various types of lavas, sediments—some of which contain pebbles of a still more ancient granite—and metamorphosed equivalents. The history of the Series appears to have been quite extended. Consequently, some support is given to Holmes'[14] estimate of 3,350 × 10^6 years as the age of the earth, rather than an age of 2,000 × 10^6 years which is sometimes considered to be the most probable age.

Text-book Organic Chemistry

No author or editor, unless claiming omniscience, completes a text-book on organic chemistry without feeling that sprinkled through his text are erroneous, inaccurate or ambiguous statements. To confirm his forebodings comes the letter from Prof. C. K. Ingold[1] and his colleagues with the above slightly unkind title, conveying the impression that text-books often contain a peculiar if not spurious brand of organic chemistry: "clauts o' cauld parritch", as Andrew Fairservice described another kind of doubtful doctrine. But surely the tone of the letter is in places exaggerated. Neither error quoted constitutes a "howler" or solecism; and far from being "inexcusable" it is easy to understand that, despite all vigilance, erroneous statements should sometimes be made or repeated, especially should they enjoy the sanction of authoritative reference books such as Heilbron's "Dictionary".

Nevertheless, Prof. Ingold's letter is salutary and is to be welcomed, both for raising an important problem and for contributing towards its solution. It is to be hoped that students, teachers and research workers will assist authors to overcome sins of omission and commission, either by private letter or by communication to appropriate journals. In the latter case, may the plea be made for publication in a prominent and accessible form. Prof. Ingold's letter complies with this requirement: his previous communication[2] on the same subject, consisting of a few lines in the middle of a longish, partly polemical paper, does not.

ARCTIC AEROBIOLOGY

By Prof. NICHOLAS POLUNIN, Prof. S. M. PADY and Prof. C. D. KELLY

McGill University, Montreal

SO far as we are aware, the only published observations on the presence of micro-organisms or spores in the atmosphere overlying arctic regions are those of Meier[1,2], who investigated petrolatum-coated slides exposed by Colonel Charles A. Lindbergh during his flights over southern and central Greenland, etc., in the summer of 1933. Meier's preliminary account[1] indicated that a considerable diversity of biota was represented on Lindbergh's slides, which in most instances had been exposed for at least an hour above 2,000 ft. from an aircraft travelling at an airspeed of 110 m.p.h. Unfortunately Meier lost his life in a flying accident before the promised detailed account of this interesting material could be written. He did, however, remark[1] that in spite of the nutritionless surface "Some of the spores of fungi caught at different points show definite evidence of having been alive when trapped. . . . The potentialities of world-wide distribution of spores of fungi and other organisms caught up and carried abroad by transcontinental winds may be of tremendous economic consequence."

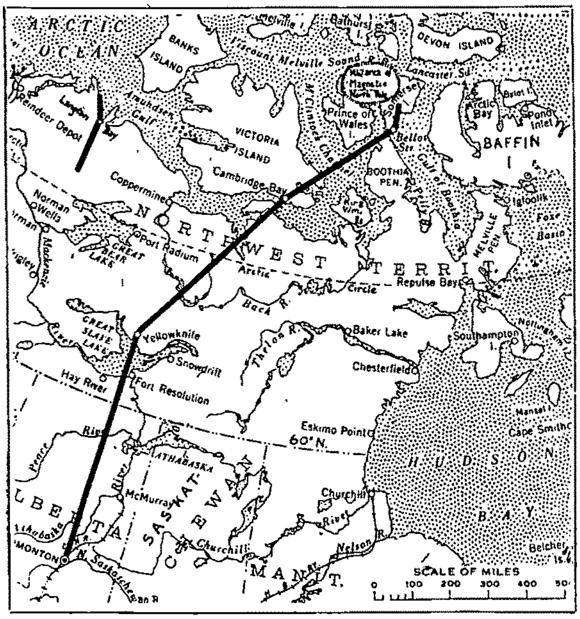
It was also in 1933 that one of us (N. P.) exposed nutrient Petri plates on mountain tops in northern Lapland under winter conditions, and later in Spitsbergen during the summer. But with the protracted travels and rough treatment which the plates had undergone, and the crudity of the only methods of incubation available in the field, it was felt that the unexpected number of fungal and bacterial colonies observed in some cases after only brief exposure might be due to contaminations, and so no account was published. Indeed, no reliance could be placed on these 'observations', as many of the plates appeared to be far from sterile before exposure, while in others the medium had become hardened through loss of water. However, the attempts are mentioned here as they appear to represent the first (albeit abortive) ones of their kind in the arctic and already give some suggestion of relatively abundant life in its atmosphere.

During August and September 1947, one of us (N. P.), while flying with the Royal Canadian Air Force on operations concerned primarily with geographical survey work and locating the north magnetic pole, took the opportunity of exposing from his aircraft considerable numbers of nutrient Petri plates and 'Vaselined' microscope slides especially prepared under the direction of another of us (S. M. P.). The medium employed on the plates was Czapek's solution agar with sugars omitted but with the addition of 1·0 gm. of yeast extract per 1,000 c.c., allowing only very slow growth and consequently temporary storage of the plates in the field. Two batches of nutrient plates were used in the investigation, the first being taken up with the main expedition in June, and the second being flown into the field in July. Contaminations developed in some of the plates of the first set, and these contaminated plates were consequently discarded; the second set, on the other hand, did not develop any contaminations whatsoever. Moreover, all the seven unexposed plates proved to be sterile even after they had been returned to the laboratory and incubated in mid-September. A total of fifty-one plates and fifty-two slides were exposed.

Each plate was doubly wrapped in wax and tissue papers, and was unwrapped only just before, and rewrapped immediately after, exposure, which was entirely outside the aircraft. All wrappings were secured with rubber bands, and except during exposure each cover was attached to its plate by adhesive tape, which also proved convenient for labelling purposes. An exposure was effected by thrusting the unwrapped but still covered plate in the right hand from a partially open window on the starboard side of the aircraft, holding the plate with the nutrient surface orientated vertically and hence 'flat' against the air-stream at least eight inches from the nearest point of the fuselage, then easing off the cover with the left hand and sliding it away down the right wrist and forearm, which were thus made to withstand the pressure of the air on the left hand holding the cover. The exposed plate was thus held against the full force of the airstream for precisely two minutes, after which it was covered by a reversal of the previous operation of the left hand and then brought into the aircraft to be finally labelled and wrapped. With the method evolved and precautions taken, and as was indicated by the seven controls mentioned above, there seems virtually no possibility of more than an occasional contamination.

The 'Vaselined' slides were kept in individual, specially constructed cardboard and adhesive-tape containers separately wrapped in wax paper which allowed no access of air currents until they were opened before placing the whole in a special wooden-handled, copper holder in which the sticky surface was exposed against the air-stream for five minutes in about the same position outside the aircraft as the nutrient plate: indeed, each slide and plate formed a pair, being exposed either contemporaneously or consecutively according to the type of aircraft and facilities immediately available.

Except for inevitable gaps due to liquid or ice precipitation or to preoccupation with landing, etc., a plate and a slide were exposed either every twenty or every thirty miles, approximately, throughout the flights concerned. The first of these flights was on August 12, and extended in a northerly direction from a base-camp situated on an unnamed lake north-west of Great Bear Lake to Langton Bay on the Arctic Ocean coast, and thence in a north-westerly direction to the mouth of the Horton River near Cape Bathurst, the most northerly point of the western Canadian mainland. These early exposures (numbers 1–11) were made at approximately twenty-mile intervals from the side of a 'Norseman' aircraft fitted with floats and may have been affected by bodies adhering to the fuselage or by the turbulence caused by the single propeller situated ahead of the nose, although such a possibility has been largely discounted by others[1,3]. The later exposures, comprising the vast majority in all, were made from the co-pilot's seat of a 'Canso' flying-boat of which no part lay directly ahead: the propellers stood above and well behind, and the smooth nose was situated so far below and to the side of the point of exposure that the air-stream in normal circumstances seemed entirely steady and direct. These later exposures extended over about 1,500 miles from Somerset Island southwards to Edmonton, Alberta, and were made up of three groups on flights as follows: (1) on August 26, at approximately twenty-mile intervals from Cambridge Bay, Victoria Island, in a north-easterly direction to the south end of Somerset Island, then northwards until bad weather intervened in about latitude 73° N.; (2) on August 27 at approximately thirty-mile intervals from Cambridge Bay in a south-south-westerly direction to Yellowknife, Northwest Territories; (3) on September 5, at approximately thirty-mile intervals, from Yellowknife southwards to Edmonton. These flights, on which plates and slides were exposed, are indicated on the accompanying sketch-map.



Most of this 1947 exposing was done at or around an altitude of 5,000 ft. and airspeed 100 knots (115 m.p.h.). Details were also kept, or are being worked out, of other conditions such as wind, cloud, icing, geographical position, etc., and it is hoped through official channels to gather together sufficient extra-continental meteorological data on the 'upper air' movements of these and preceding days to get some indication of the general region of origin of the air-masses in and below which the plates and slides were exposed. Meanwhile the slides are being sent to specialists to examine for stem and leaf rust of wheat and other pathogen spores, pollen grains, etc., while we are dealing in the first instance with the considerable range of Fungi and Bacteria that are represented on the plates. Indeed, whereas we had expected few or no colonies to develop on incubation of the plates that had been exposed in the far north, for example, over the ice-fields of M'Clintock Channel, we found that almost all on return bore numerous and various colonies of Fungi and Bacteria, indicating both these groups to be abundantly and diversely represented in the arctic atmosphere. As examples we may note that plate No. 25, exposed at 4,000 ft. over the south coast of Somerset Island around latitude 72° N. and longitude 94° W., shows a total of 102 colonies of Fungi and 89 of Bacteria, while plate No. 17, exposed at 4,400 ft. over the sea-ice of M'Clintock Channel, shows 7 colonies of Fungi and 95 of Bacteria. On the other hand, plate No. 24, exposed only ten minutes earlier than No. 25 and in essentially the same region, shows only 8 fungal and 74 bacterial colonies.

Determinations and other details will take a considerable time to work out; but we would like meanwhile to report this unexpected indication of abundance of life in the arctic air and say that we hope to extend these studies in the future, and request news of any connected work.

DIELECTRIC RESIDUAL EFFECTS IN TITANATES

By Prof. J. R. PARTINGTON, M.B.E., G. V. PLANER and I. I. BOSWELL

Queen Mary College, University of London

BARIUM TITANATE and certain related compounds having structures of the perovskite type possess exceptionally high permittivities which rise to a maximum at certain characteristic temperatures, a transition taking place from a distorted to a cubic crystal structure. The permittivity – temperature relation depends primarily on the particular material used, but is influenced also by the method of preparation, especially by the temperature at which the ceramic is fired. It has been shown that barium titanate is ferro-electric below the temperature corresponding to its permittivity maximum[1,2], and in this connexion a study of the changes with time in the permittivity and dielectric losses after a high, unidirectional electric field had been applied to materials of this type, which is now described in outline, may be of interest.

The experimental method consisted in maintaining the samples at different temperatures and determining the permittivity and dielectric losses before, and at various times after, the application of a strong D.C. field. Accurate temperature control was essential owing to the high temperature coefficient of permittivity, and a special thermostat arrangement was used, comprising a small metal chamber containing the sample, through which dried air at a constant temperature was passed. The permittivity and losses of the dried solid were determined at a frequency of 1 kc./s. and measuring tensions not exceeding 5 V./3 mm. Immediately after the application of the high tension, the electrodes of the samples were in all cases connected to earth for some seconds.

Barium titanate and a number of mixed titanates were examined, and it was found that below the temperature corresponding to the permittivity maximum, $T_{\varepsilon \max}$, the permittivity, shortly after the application of a high tension, had a value 3–6 per cent above that prior to treatment, and reverted at first rapidly, later more slowly, to its original value. The total time of decay varied from 10 to 50 min. from the time of cessation of the high tension.

Figs. 1 and 2 show the type of curves obtained for samples A and B, consisting of barium titanate with a permittivity peak at 112° C., and a mixed titanate with a maximum at 50° C., respectively. The effect became more pronounced at higher temperatures, being largest at a temperature just below $T_{\varepsilon \max}$. The time of reversion to the original permittivity was increased by prolonging the period of application of the tension. In the case of barium titanate, effects

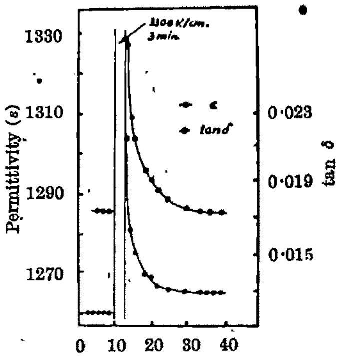

Fig. 1. SAMPLE *A*: TEMP. 24° C.; D.C. FIELD, 3300 V./CM., APPLIED FOR 3 MIN.

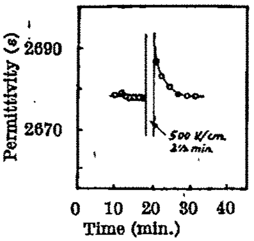

Fig. 2. SAMPLE *B*: TEMP. 24° C.; D.C. FIELD, 500 V./CM., APPLIED FOR 2½ MIN.

of the same type were observed at temperatures corresponding to the portion of the plateau in the permittivity – temperature curve in which the temperature coefficient is slightly negative (that is, between 20° and 45° C.), and in the regions where the coefficient is positive. The dielectric losses and permittivity in each case varied in a similar manner, approaching very nearly their original value after a period of 10–50 min.

At temperatures above $T_{\varepsilon\max}$, the permittivity was smaller immediately after the cessation of tension and reverted slowly to its original value, the effect being largest in the case of higher tensions and prolonged periods of application. Figs. 3 and 4 show typical curves obtained for sample *C* consisting of barium strontium titanate ($BaTiO_3 : SrTiO_3 = 75 : 25$, by weight; $T_{\varepsilon\max}$: 21·5° C.), and sample *B* ($T_{\varepsilon\max}$: 50° C.). Analogous results were obtained with all the compositions examined, the only exception being sample *C* at a temperature just above $T_{\varepsilon\max}$, which showed a temporary increase in permittivity. The loss tangent, being low beyond $T_{\varepsilon\max}$, remained constant at a value of 0·0025 and 0·001 in the case of samples *B* and *C*, respectively.

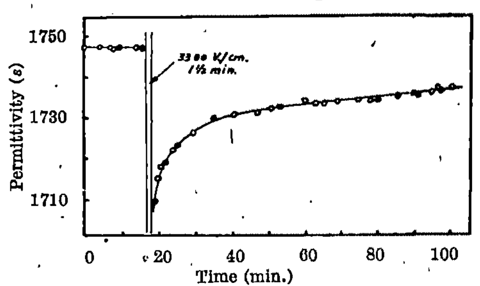

Fig. 3. SAMPLE *C*: TEMP. 70° C.; D.C. FIELD, 3300 V./CM.; APPLIED FOR 1½ MIN.

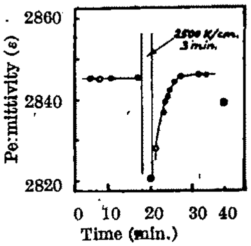

Fig. 4. SAMPLE *B*: TEMP. 80° C.; D.C. FIELD, 2500 V./CM., APPLIED FOR 3 MIN.

It is seen that, within the temperature range corresponding to the distorted perovskite structure, a temporary increase in permittivity was obtained, while in the region of the cubic structure a temporary decrease was generally observed. A possible explanation for the increase at a temperature just above $T_{\varepsilon\max}$ in the case of sample *C* may be that the two structures co-exist within a temperature range extending slightly beyond $T_{\varepsilon\max}$[3,4], the effect due to the distorted structure being the larger one.

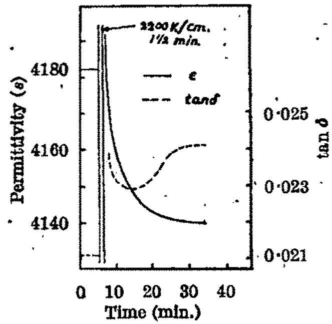

Fig. 5. SAMPLE *D*: TEMP. 30° C.; D.C. FIELD, 2200 V./CM., APPLIED for 1½ MIN.

At a temperature below $T_{\varepsilon\max}$, a third effect was observed in the case of some compositions after the application of tensions higher than those resulting in the temporary increase in the permittivity only. Under these conditions, the permittivity approached asymptotically an apparently permanent lower value. Fig. 5 shows this effect, combined with the initial temporary increase, for sample *D* having a permittivity maximum at 50° C.

A fuller account of the work will be published later.

We are greatly indebted to the United Insulator Co., Ltd., Surbiton, for generously giving us facilities in their Research Laboratory.

INTERNATIONAL TIMBER CONFERENCE

A REPORT has been issued of the International Conference on Timber held at Marianski Lazne, Czechoslovakia, during April 28–May 10, 1947, under the auspices of the Food and Agricultural Organisation of the United Nations (Washington, D.C.: Food and Agriculture Organisation. 50 cents). These discussions, the first comprehensive discussions of timber and forestry to be held in Europe since the end of the War, have shown that the nations represented were in unanimous agreement on a variety of issues. The Conference did not attempt to solve all the problems of forests and timber in Europe, but confined its attention to more limited objectives and admitted that, even with respect to these, its recommendations were only a starting point.

It is well known that post-war Europe is confronted with a grave timber problem. It is not a matter, as some appear to think, of merely seeking out accessible sources of supply and cutting the forests down. The large excess fellings and destruction committed during the War has led to a serious position in parts of Europe and outside Europe. Excess fellings—cutting out more than the annual increment of one or more years—means in the end the disappearance of a forest. Even to supply the well-known needs for timber of large populations we should not be justified in dooming forests which should be maintained in the interests of posterity and often for reasons quite other than timber alone.

For Europe alone it was known that more timber annually is required than pre-war Europe used; yet the soft-wood timber supplies are below the average of the year before 1939. This is delaying reconstruction. Methods of bridging the gap, it was realized, appeared to be not only inadequate but also difficult to achieve; there was also the fear that repercussions might lead to an even more serious crisis in the future; in other words, over-cutting after the drain imposed on the coniferous forests during the War might lead to lasting damage to the surviving European forests. The second alternative appeared equally difficult: a reduction in timber consumption was equally undesirable, since it is in apparent conflict with improvement in housing and living standards which has been adopted as a primary objective by the United Nations Organisation. The Conference approached this matter by dividing it into three parts: (1) short-term problems; (2) long-term problems; and (3) further procedure; and the three chapters of the report deal with the problems in this manner.

The Belgian delegate reported on savings effected by substituting other materials for lumber. A memorandum was submitted by the United Kingdom on economy and the uses of timber, including restrictions and the fixing of maximum sizes in which timber is to be used for joists, rafters, floor-boards and so forth. Some of these restricted efforts, it may be said, have not proved very satisfactory, and do not help in reconstruction on the countryside.

A note had been drawn up by the Food and Agriculture Organisation Preparatory Commission on World Food Proposals, and briefly this report stated that the timber situation presents the same problem which has confronted the Commission in regard to several other commodities with, says the report, "the important difference that as food scarcities begin to subside, the world-wide timber shortage is becoming more serious".

It is suggested in the present report that a better organisation for distribution and allocation, by transport and credit facilities, would assist in some degree; the introduction of technical improvements in order to ensure better utilization of available timber supplies would also be valuable.

There is another resolution submitted by the Economic and Social Council of the United Nations, recognizing the seriousness of the present timber shortage in Europe which threatens to delay economic recovery, and this resolution welcomes the initiative taken by the Food and Agriculture Organisation. It is not possible here to deal in detail with all the resolutions and recommendations adopted by the Conference; but briefly they refer to various details in forest management and to the necessity for dealing with the world-wide shortage of timber in such a manner that serious depredations will not be made on the forests, which would result in their destruction. It is also recommended that proper organisation and proper technical methods should be introduced into the management of forests, and having regard to the long period required for the development of forest resources and for the fulfilment of domestic rational forest policies, it is considered desirable "that the European countries concerned should meet together from time to time to exchange information and views about their problems in the field of medium- and long-term forestry. F.A.O. under its existing mandate is able to call together consultative committees, and it would seem appropriate therefore that F.A.O. should consider providing such a committee on forestry within its framework. It could meet from time to time as might seem necessary in the opinion of F.A.O. and of the governments concerned acting in close consultation."

E. P. STEBBING

SCIENTIFIC APPROACH TO THE LACE INDUSTRY

IN its treatment of scientific and technical research and development, the report of the Board of Trade Working Party on the Lace Industry[*], of which Miss L. S. Sutherland was chairman and the late Prof. J. M. Gulland a member, follows similar lines to earlier reports from 'working parties' dealing with other textile industries. Like most of the latter, the machine-lace industry grew out of a craft, that of traditional hand-lace, and was not born of scientific research. In addition, it has always been, and still is, essentially a cotton industry, and in its essentials the industry remains the same as in the days of our grandfathers.

Speaking in very broad terms, in the past the lace industry in Britain has shown little interest in research. The total expenditure by individual firms on research appears to be small, and contribution to co-operative research by membership of research institutes such as the British Cotton Industry Research Association was by no means universal although fairly common. In spite of signs of a changing attitude in recent years, the 'working party' attributes many of the present urgent problems of the industry to its failure over a long period to investigate systematically and scientifically the textile, engineering and other aspects of the trade, not least important being those affecting health. One of the strongest recommendations in the report is, in fact, that the newly formed Research Council for the industry should press forward its investigations into a satisfactory substitute for graphite, the use of which as a lubricant for lace machines has given the machine-holding sections the character of a 'dirty trade'.

In characterizing the lace industry as a whole with indifference to research, with neglect of fundamental research and with a marked tendency for whatever research is prosecuted to be sporadic, and noting the absence of research staff and, except in the dressing section, even of scientific staff, the 'working party' frankly recognizes that no industry could achieve products of such technical excellence as lace fabrics without a background of continual inquiry and trial. None the less, it is questionable whether inquiries into the use and handling of different yarns have in general been prosecuted with sufficient system to yield their full potential value. Investigations are frequently short-term projects to solve specific production problems, and are shelved when these have been overcome sufficiently for the immediate needs.

---

[*] Board of Trade. Working Party Reports: The Lace Industry. (London: H.M. Stationery Office, 1947.) 3s. 6d. net.

Valuable services have indeed been rendered to many firms by the Textile Testing Department, until very recently a part of University College, Nottingham, and by several research associations, but the 'working party' suggests that there are at least four factors restricting the development of research in the industry as a whole. As in the cotton industry, there has been lack of contact between the machine-holders and the machine-builders; the industry is almost entirely lacking in scientifically trained personnel in its higher ranks; the intense individualism of the industry has prevented a united approach to technical and other mutual improvements; and lastly, many machine-holders have taken a narrow view of their functions—to regard their function as limited to processing yarn supplied to them in a finished state with machinery planned and built by others, and to consider in consequence that little or no investigation is required of them other than innovations in design and yarn utilization, and handling.

These factors have to some extent been weakened by experience gained in co-operative research and production during the War, and the formation in January 1944 of a Technical and Research Committee of the Federation of Lace and Embroidery Employers' Associations led in June 1945 to the formation of a Lace Research Council, consisting of the members of the former Committee and the professors of botany (industrial mycology), chemistry, electrical engineering, physics and textiles of the University College of Nottingham. The Federation, however, was not disposed at that stage to establish a research association under the Department of Scientific and Industrial Research, but having guaranteed an income of £2,000 per annum for a period of three years, the Federation approached the latter Department to obtain Government assistance. As a result of this approach, the Research Council will have at its disposal a total income of £4,500 per annum during the three-year period and has already appointed as liaison officer in research matters a chemist of long experience of textile processes. The Council has, however, no laboratories and the duties of this solitary scientific officer are in the first place confined to formulating the problems and conditions facing the industry, maintaining contact with research associations and inaugurating investigations under contract at universities, technical colleges and elsewhere, and to the dissemination of information.

That, broadly, is the position which the 'working party'—whose conception and differentiation of research is in line with those detailed in the report of the Cotton Working Party—seeks to meet by what has now come to be the customary prescription of 'working parties', namely, a compulsory levy. It does not, indeed, suggest that a compulsory levy should be made solely for scientific and technical research: it is also intended to cover the financing of economic and market research, the promotion of overseas sales and the establishment of a design and fashion centre. The 'working party' does not go further than to suggest that the question whether the industry can afford not to inaugurate a fully fledged research association with its own staff, laboratory and workshop should be under constant review. It does not appear, however, to have contemplated any alternative to the usual research association for an industry in which much educational work is imperative before support can be won for research, and utilization of the results of research ensured.

COLOUR PHENOMENA IN THE PERCEPTION OF FINE DETAIL

In a recent memoir, "The Visual Perception of Fine Detail", Prof. H. Hartridge has discussed the way in which "the image formed on the retina is clarified and improved before it reaches the higher centres of the brain", and considers in particular the reason why objects in white light are not seen surrounded by the coloured fringes which are certainly produced by the aberrations of the dioptric system of the eye (*Phil. Trans. Roy. Soc.*, B, **232**, 519; 1947). To throw light on this question, observations were made of the changes in apparent colour of coloured test objects, in some cases monochromatic stimuli, when their angular size was greatly reduced and when other factors—the brightness of the background, the proximity of other coloured objects, the pupil size, etc.—were modified.

While some of the results will be familiar to readers of Helmholtz ("Physiologische Optik", 2, 128 and 239–41, 3rd Edit.), many new observations are reported, and it is shown how they fit in with the apparent absence of fringes in ordinary vision. After skittling down a number of alternative hypotheses, Prof. Hartridge puts forward his own explanation of the changes in apparent colour. His 'neurological hypothesis' postulates four nervous mechanisms (antichromatic responses) which operate locally in all parts of the fovea and parafovea and the function of which is to control the connexion between photo-receptors and cranial centres. Thus the connexion between medium-wave receptors and the cranial centre for short waves is controlled by the 'yellow' mechanism, that between short-wave receptors and their cranial centre by the 'blue' mechanism. The mechanisms may also act together: the 'red' and 'green' mechanisms acting together change colourless vision to reduced (so-called diochromatic) vision, and 'yellow' and 'blue' mechanisms acting together then alter the latter to full colour vision. The neurological hypothesis is not a simple one, and without the answers to several questions, which Prof. Hartridge does not provide, it is difficult to form even a crude picture of the way the mechanisms work. It is not clear, for example, whether they have end-organs of their own or whether they must receive nervous stimuli from the photo-receptors which they are connecting or disconnecting with the cranial centres. More specific assumptions would seem necessary if any quantitative development of the hypothesis is to be possible.

To answer another main question, namely, the reason why at high intensities visual acuity depends so little on the colour of the light, Prof. Hartridge suggests that retinal receptors of each particular type (spectral response) tend to be collected in small clusters. Thus to see fine detail in blue light, the retinal image is brought on to a cluster of 'blue' receptors; but if red light is used, there is a slight change of fixation to bring a cluster of 'red' receptors into action. Several experiments were made showing that slight changes in the direction of fixation for lights of different colours do occur. These changes in fixation, together with the changes observed in the apparent colour of very small test stimuli, are also regarded by Prof. Hartridge as strong evidence for the existence in the human retina of some seven types of receptor with narrow spectral sensitivity curves analogous to the modulator curves obtained in Granit's electrophysiological studies on animals (polychromatic theory of human vision).

One difficulty with this paper is that Prof. Hartridge has not only lost faith in the trichromatic theory, but he has also, it seems, abandoned the whole mode of approach through colour-matching measurements by which the purely empirical structure of the theory has been built up. One feels that the new ideas, if valid, must interlock with this empirical structure; but Prof. Hartridge does not show that they do.

W. S. Stiles

FRUIT AND VEGETABLE CULTURE

THE annual report for 1945 of the Agricultural and Horticultural Research Station at Long Ashton, Bristol, gives results of the Station's work on the scientific horticulture of fruit and vegetable crops and on their products.

Classification of the visual symptoms of mineral deficiencies of crop plants is continued by E. J. Hewitt. He uses various refinements in technique, including a 'Permutit' demineralization method of purifying rain-water for studies of iron deficiency, and a method for transplanting adult plants without root disturbance. The present survey embraces deficiencies of twenty-nine crops grown in sand culture, and one incidental result is that a high nitrogen-level accentuates the symptom expressive of boron deficiency. Some of the effects of soil acidity on crops are not yet fully understood, and Hewitt also has a progress report on this matter. It would seem that some at least of the symptoms of acid damage are those of manganese toxicity, and other interesting tentative conclusions are mentioned. D. J. D. Nicholas has investigated the validity of rapid chemical tests for the diagnosis of mineral deficiencies in potato plants. He finds a welcome accord with the results of the full chemical analysis, and with the visual symptoms. Several useful correlations between deficiencies and toxicities are established. Spraying the foliage of tomato crops with 2 per cent magnesium sulphate solution is found to be a much better control of magnesium deficiency than soil applications of the same substance, according to D. J. D. Nicholas, J. O. Jones and T. Wallace. The director of the Station, Prof. T. Wallace, with E. Catlow, gives two extensive reports on the manuring of potatoes and garden beet respectively.

A useful classification of power-operated hydraulic spraying machinery for fruit crops has been prepared by H. G. H. Kearns. He gives broad specifications for the chief components of spray outfits, and estimates the biological requirements of spraying. Growers should find this paper a useful practical guide to the choice of this section of equipment. The advent of D.D.T. and benzene hexachloride makes it necessary to find the best methods of incorporating these sprays in a comprehensive programme. H. G. H. Kearns, R. W. Marsh and H. Martin have made experiments on this problem, which rather suggest that D.D.T. is an excellent insecticide against certain pests, but offers no widespread panacea of control. It was effective against leaf-curling aphids. Comparisons of three fungicides—tetramethylthiuram, ferric dimethyldithio-carbamate, and copper sebacate—were also included. The last-mentioned was approximately equal to lime sulphur as a fungicide. Other papers in this section deal with the flight period of the codling moth in relation to time of spraying (S. H. Bennett), the effect of early lifting and other factors on storage losses of onions (H. E. Croxall), attack of lettuce by two strains of the fungus *Bremia lactucæ*, and the relation of the disease to wild species of *Lactuca* (L. Ogilvie), and clover-rot investigations by Moira Munro and L. Ogilvie. The general features of eelworm attacks of vegetable crops are reviewed by H. W. Miles and Mary Miles, and A. J. Lloyd briefly outlines results of a biological method of estimating the intensity of clover stem eelworm infections in field soils. A short paper by May J. Haddock shows that the 'turnip flea beetle' is not a single species, but a complex of as many as eight species. They all seem to have a wide taste for cruciferous plants; but this numerical expansion of species does not seem to offer any change in methods of control.

The Station has also investigated problems relating to fruit and vegetable products. Workers in this field will find papers on the control of blackening of boiled potatoes, factors affecting quality in potatoes and tomatoes, the apple as a source of vitamin C, and the Station's major cider research.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Laboratory Assistant (Grade II) in the Department of Chemistry—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1 (December 29).

Veterinary Inspectors in the Ministry of Agriculture for Northern Ireland—The Secretary, Civil Service Commission, Stormont, Belfast (December 31).

Assistant Chemist in the Chiswick Laboratory—The Staff Officer (ER/E. 457), London Passenger Transport Board, 55 Broadway, London, S.W.1 (December 31).

Senior Lecturer, and a Reader, in Agriculture, at Makerere College, East Africa—The Secretary, Inter-University Council for Higher Education in the Colonies, 8 Park Street, London, W.1 (December 31).

Qualified Chemists in the Generating Stations at Chelsea and Neasden—The Staff Officer (ER/E. 454), London Passenger Transport Board, 55 Broadway, London, S.W.1 (December 31).

Bacteriologist to take charge of a public health laboratory service in Belfast—The Establishment Officer, Ministry of Health and Local Government, Stormont, Belfast (December 31).

Research Fellow to work on the problem of origin and measurement of stresses in cast metal products—The Professor of Industrial Metallurgy, The University, Edgbaston, Birmingham 15 (December 31).

Demonstrator (part-time) in the Pharmacology Department—The Dean, Guy's Hospital Medical School, London, S.E.1 (December 31).

Lecturer in Anatomy at Makerere College, East Africa—The Secretary, Inter-University Council for Higher Education in the Colonies, 8 Park Street, London, W.1 (January 1).

Lecturers (2, Grade IIc or IIb) in Chemical Engineering—The Secretary, The University, Edmund Street, Birmingham (January 1).

Lecturer (Grade IIc) in Pharmacology—The Secretary, The University, Edmund Street, Birmingham 3 (January 8).

Scientific Officer in the Blood Transfusion Laboratories, Manchester—The Regional Transfusion Officer, Royal Infirmary, Manchester 13 (January 10).

Lecturer (Grade IIc) in Electrical Engineering—The Secretary, The University, Edmund Street, Birmingham 3 (January 10).

Senior Scientific Officer or Scientific Officer (Ref. No. A.337/47), and a Senior Experimental Officer or Experimental Officer (Ref. No. F.773/47), at the Atomic Energy Research Establishment, Harwell, Didcot, Berks—The Ministry of Labour and National Service, Technical and Scientific Register, Room 669, York House, Kingsway, London, W.C.2, quoting appropriate Ref. No. (January 10).

Director of a new Vegetable Research Station—The Chairman. Organising Committee, Vegetable Research Station, Ministry of Agriculture, Block 4, Bickenhall Mansions, Baker Street, London, W.1 (January 24).

DEPUTY CHIEF FUEL ENGINEER, London (male)—The Director of Establishments, Ministry of Fuel and Power, 7 Millbank, London, S.W.1, quoting 'Deputy Chief Fuel Engineer' (January 29).

PRINCIPAL MEDICAL OFFICER (Research), MEDICAL OFFICERS (Research, 3), a PRINCIPAL SCIENTIFIC OFFICER, SENIOR SCIENTIFIC OFFICERS (4), and EXPERIMENTAL OFFICERS (6), in the Chemical Defence Experimental Station, Porton, Wilts—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2075 (January 29).

CHANDOS PROFESSOR OF PHYSIOLOGY in the United College—The Secretary, The University, St. Andrews (February 28).

LECTURER IN STATISTICS—The Registrar, Trinity College, Dublin (March 1).

CHAIR OF GEOGRAPHY—The Registrar, University College, Exeter.

DEMONSTRATORS (2) IN THE DEPARTMENT OF BIOCHEMISTRY AND CHEMISTRY—The Dean of the Medical College, St. Bartholomew's Hospital, West Smithfield, London, E.C.1.

PLANT PATHOLOGIST for the East African Groundnut Scheme—The Personnel Manager (Technical), United Africa Co. (Managing Agency), Ltd., Unilever House, London, E.C.4.

HEAD LABORATORY TECHNICIAN, Grade A (organic or medical chemistry)—The Director, Wellcome Laboratory of Human Nutrition, Churchill Hospital, Oxford.

TECHNICIAN IN THE DEPARTMENT OF PHYSICS—The Secretary, University College London, Gower Street, London, W.C.1, quoting Physics/1.

PHYSICIST, PHYSICAL CHEMISTS (2), an ORGANIC CHEMIST, and a TEXTILE TECHNOLOGIST—The Acting Secretary, British Rayon Research Association, Bridgewater House, 58 Whitworth Street, Manchester 1.

ASSISTANT PUBLICATIONS OFFICER to deal with the editing, publication and distribution of research reports—The Secretary, Medical Research Council, 38 Old Queen Street, London, S.W.1.

METALLURGIST FOR THE LIAISON AND TECHNICAL SERVICE DEPARTMENT, and an INVESTIGATOR IN THE ANALYTICAL DEPARTMENT—The Secretary, British Non-Ferrous Metals Research Association, 81–91 Euston Street, London, N.W.1.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Imperial Bureau of Animal Breeding and Genetics, Edinburgh. Technical Communication No. 5: Gestation Periods; a Table and Bibliography. Compiled by Dr. J. H. Kenneth. Second edition. Pp. 30. (Aberystwyth: Imperial Agricultural Bureaux, 1947.) 3*s*. [94

Manchester Joint Research Council. Communication Series No. 2: Report of Conference on Research and the Smaller Firm, held on Wednesday, 16th October 1946, at the Albert Hall, Manchester. Pp. 102. (Manchester: Manchester Chamber of Commerce, 1947.) 2*s*. 6*d*. [94

The Road Back to Health: the Story of Medical Rehabilitation. (Published for the Ministry of Health.) Pp. 28. (London: H.M. Stationery Office, 1947.) 6*d*. net. [94

Forestry Commission. Bulletin No. 13: Studies on Tree Roots. Reprint. Pp. 72 + 17 plates. (London: H.M. Stationery Office, 1947.) 3*s*. 6*d*. net. [94

Ministry of Fuel and Power: Safety in Mines Research Board. Paper No. 105: The Prevention of Coal Dust Explosions, Part 1: The Effect of Manner of Distribution of Stone Dust. By S. Jones and F. V. Tideswell. Pp. 24. (London: H.M. Stationery Office, 1947.) 6*d*. net. [154

Federation of British Industries. Industrial Research in Technical Colleges. Report of a Special Sub-Committee of the F.B.I. Industrial Research Committee. Pp. 22. (London: Federation of British Industries, 1947.) [154

Watford Industrial Exhibition. Opened on 5th June 1947 by the Rt. Hon. Lord Brabazon of Tara and continuing until 18th June. Pp. 60. (Watford: Town Hall, 1947.) [154

The Life and Work of George Gerald Henderson. By Prof. Sir Ian Heilbron. (First Henderson Memorial Lecture.) Pp. 12. (London: Royal Institute of Chemistry, 1947.) [154

The History and Prevention of Silicosis, with Special Reference to the Witwatersrand. By Dr. A. J. Orenstein. (First Sir Julius Wernher Memorial Lecture.) Pp. 19. (London: Institution of Mining and Metallurgy, 1947.) [154

Reports of the Council and Auditors of the Zoological Society of London for the Year 1946. Pp. 40. (London: Zoological Society of London, 1947.) [174

Department of Scientific and Industrial Research: Standing Consultative Conference on Fuel Research. Fuel Abstracts. New Series, Vol. 1, No. 1, January: Abstracts Nos. 1 to 522 and Subject Index. Pp. ii + 128 + xvi. (London: H.M. Stationery Office, 1947.) 50*s*. per annum. [174

British Electrical and Allied Manufacturers' Association. Report of the Council for the Year 1946–47. Pp. 32. (London: British Electrical and Allied Manufacturers' Association, 1947.) [174

John Innes Horticultural Institution, Merton and Hertford. Thirty-seventh Annual Report, 1946. Pp. 32. (London: John Innes Horticultural Institution, 1947.) [174

Further Education: a Monthly Review of Planning and Progress. Vol. 1, No. 1, April. Pp. 24. (London: Turnstile Press, Ltd., 1947.) 1*s*. 6*d*. net. [224

Other Countries

Carnegie Institution of Washington. Publication 551: Contributions to Paleontology—Fossil Vertebrates from Western North America and Mexico. By E. L. Furlong, E. Raymond Hull, Lore Rose David, Robert E. Wallace and Hildegarde Howard. Pp. iii + 195 + 31 plates. (Washington, D.C.: Carnegie Institution, 1946.) 2.50 dollars. [313

Smithsonian Institution: United States National Museum. Bulletin 191: Life Histories of North American Jays, Crows and Titmice, Order Passeriformes. By Arthur Cleveland Bent. Pp. xi + 495 + 68 plates. (Washington, D.C.: Government Printing Office, 1946.) [313

A Five Year Plan for the Geological Survey of India: Memorandum on the Expansion and Reorganisation of the Geological Survey of India. Pp. ii + 25. (Calcutta: Government of India Press, 1946.) [313

Ministry of Public Works, Egypt: Physical Department. Paper No. 51: The Nile Basin. By Dr. H. E. Hurst, R. P. Black and Y. M. Simaika. Vol. 7: The Future Conservation of the Nile. Pp. xv + 178 + 27 plates. (Cairo: S.O.P. Press, 1946.) P.T. 125; 25*s*. [313

Report of His Majesty's Astronomer at the Cape of Good Hope to the Secretary of the Admiralty for the Year 1942. Pp. 6. Report of His Majesty's Astronomer at the Cape of Good Hope to the Secretary of the Admiralty for the Year 1943. Pp. 7. Report of His Majesty's Astronomer at the Cape of Good Hope to the Secretary of the Admiralty for the Year 1944. Pp. 8. (Cape of Good Hope: Royal Observatory, 1943–1945.) [94

Smithsonian Miscellaneous Collections. Vol. 106, No. 22: Solar Cycles. By H. H. Clayton. (Publication 3870.) Pp. ii + 18. (Washington, D.C.: Smithsonian Institution, 1947.) [94

State of California Department of Natural Resources: Division of Fish and Game, Bureau of Marine Fisheries. Fish Bulletin No. 65: Analysis of Populations of the Pacific Sardine on the Basis of Vertebral Counts. By Frances N. Clark. Pp. 26. (Terminal Island, Calif.: Department of Natural Resources, 1947.) [94

Carnegie Institution of Washington. Year Book No. 45, July 1, 1945—June 30, 1946, with Administrative Reports through December 13, 1946. Pp. xxxiv + 235. (Washington, D.C.: Carnegie Institution, 1946.) [94

Canada: Department of Mines and Resources: Mines and Geology Branch, Bureau of Mines. No. 817: Peat Moss Deposits in Canada. By Harald A. Leverin. Pp. v + 102 (9 plates). (Ottawa: King's Printer, 1946.) 25 cents. [94

Government of Cyprus. The Proceedings of a Conference on Land Use in a Mediterranean Environment, held in Nicosia, Cyprus, 16th–17th April, 1946. Pp. 55. 7*s*. Report of the Land Utilization Committee, 1946. Pp. 32. 5*s*. (Nicosia: Government Printing Office, 1946–1947.) [94

Commonwealth of Australia: Council for Scientific and Industrial Research. Bulletin No. 167: The Detonation of Nitroglycerine by Impact. By Dr. F. P. Rowden, Dr. F. Eirich, A. E. Ferguson and A. Yoffe. Pp. 44 + 8 plates. Bulletin No. 173: The Detonation of High Explosives by Impact; The Sensitivity, and the Propagation of the Explosion in Liquids. By Dr. F. P. Rowden, Dr. R. Eirich, M. F. R. Mulcahy, R. G. Vines and A. Yoffe. Pp. 75 + 34 plates. Bulletin No. 195: An Account of Experiments undertaken to Determine the Natural Population Density of the Sheep Blowfly, *Lucilia cuprina* Wied. By Darcy Gilmour, D. F. Waterhouse and G. A. McIntyre. Pp. 39 + 3 plates. Bulletin No. 196: Transmission of Potato Virus Diseases, 5, Aphid Populations, Resistance and Tolerance of Potato Varieties to Leaf Roll. By Dr. J. G. Bald, D. O. Norris and G. A. H. Helson. Pp. 32. Bulletin No. 199: The Use of Mineral Dusts for the Control of Wheat Pests. By Frank Wilson. Pp. 31 + 1 plate. (Melbourne: Government Printer, 1943–1946.) [154

Trinidad and Tobago. Empire Forests and the War. Pp. 16. (Trinidad: Government Printer, 1947.) 48 cents. [154

Institut de France: Académie des Sciences. Annuaire pour 1947. Pp. 230. (Paris: Libr. Gauthier-Villars, 1947.) [174

Forest Research in India and Burma, 1944–45. Part 1: The Forest Research Institute. Pp. iii + 149. (Dehra Dun: Forest Research Institute, 1946.) 3.8 rupees; 5*s*. 6*d*. [174

N.B.C.'s Air Castles. Pp. 52. (New York: National Broadcasting Co., Inc., 1947.) [174

Fieldiana: Geology. Vol. 10, No. 4: A New Pycnodont Fish from the Cretaceous of Arkansas. By Louis Hussakof. Pp. 23–28. (Chicago: Chicago Natural History Museum, 1947.) 10 cents. [174

Fieldiana: Zoology. Vol. 31, No. 9: Notes on Amphibians and Reptiles of Michoacan, Mexico. By Karl P. Schmidt and Frederick A. Shannon. Pp. 63–86. 25 cents. Vol. 31, No. 10: Two Races of the Bridled Titmouse. By A. J. van Rossem. Pp. 87–92. 10 cents. Vol. 31, No. 11: A New Race of Koklas Pheasant. By Robert L. Fleming. Pp. 93–96. 10 cents. (Chicago: Chicago Natural History Museum, 1947.) [174

Commonwealth of Australia: Council for Scientific and Industrial Research. Bulletin No. 198: Plant Responses to Molybdenum as a Fertilizer. 1: Molybdenum and Symbiotic Nitrogen Fixation, by A. J. Anderson and Margaret P. Thomas; 2: Factors Affecting the Response of Plants to Molybdenum, by A. J. Anderson and A. C. Oertel. Pp. 44 + 7 plates. (Melbourne: Government Printer, 1946.) [174

Sixty-third Annual Report of the Bureau of American Ethnology to the Secretary of the Smithsonian Institution, 1945–1946. Pp. 12. (Washington, D.C.: Government Printing Office, 1947.) [174

U.S. Department of Agriculture. Technical Bulletin No. 928: The Wheat Stem Maggots of the Genus *Meromyza* in the Pacific Northwest. By L. P. Rockwood, Sarah K. Zimmerman and T. R. Chamberlin. Pp. 18. (Washington, D.C.: Government Printing Office, 1947.) 10 cents. [174

Smithsonian Miscellaneous Collections. Vol. 107, No. 3: 1946–1947 Report on the 27·0074-day Cycle in Washington Precipitation. By C. G. Abbot. (Publication 3892.) Pp. ii + 2. (Washington, D.C.: Smithsonian Institution, 1947.) [174

Papers in Physical Oceanography and Meteorology published by Massachusetts Institute of Technology and Woods Hole Oceanographic Institution. Vol. 10, No. 1: Measurements of Temperature and Humidity in the Lowest 1000 Feet of the Atmosphere over Massachusetts Bay. By Richard A. Craig. (Contribution No. 362 from the Woods Hole Oceanographic Institution.) Pp. 48. (Woods Hole, Mass.: Woods Hole Oceanographic Institution, 1946.) 75 cents. [174

Annual Report of the Queen Victoria Museum and Art Gallery, 1945–1946. Pp. 6. (Launceston: Queen Victoria Museum and Art Gallery, 1946.) [75

Queensland Institute of Medical Research. First Annual Report, Year ended 30th June 1946. Pp. 8. (Brisbane: Queensland Institute of Medical Research, 1946.) [75

ORGANISATION FOR SCIENTIFIC AND INDUSTRIAL RESEARCH

SIR EDWARD APPLETON, in his A. D. Little Memorial Lecture in 1946, distinguished three types of research: free fundamental research, prosecuted in universities and similar institutions, without any regard to immediate or future application; objective fundamental research, designed to give insight and understanding rather than any special immediate practical result; and, third, applied research. He emphasized that there is no sharp differentiation between these types of research, but he finds them a more convenient classification than the older division into 'pure' and 'applied' research. The second type is carried out, as well as applied research, in Government establishments; some will also be carried out in industrial research laboratories, although in the main the latter will be carrying out applied research.

Now there are two points here of special importance in regard to the research associations which have led to doubts as to whether their expansion is wise without further inquiry and some experiment with institutions of the type of the Mellon Institute or the Institute of Paper Chemistry at Appleton, Wisconsin. As the Advisory Committee of the Privy Council noted in its first report in 1916, and as Dr. D. W. Hill points out in his recent book, a research association that fails to encourage and to inspire research activity on the part of its members fails in a vital part of its function. The research activities of the research associations may even be of secondary importance to the stimulus they give to independent research, and in assessing the value of the whole movement it is of prime importance to recognize the extent to which research has been stimulated in industry itself through their work. It is far more important to ensure that the contact and general relations between the research associations and industry, geographically and in other ways, are such as to ensure that there is the maximum interchange of information, ideas and inspiration, and that co-operation is real and not nominal, masked by payment of a subscription.

It is true that recent fiscal changes introduced by the Government may stimulate research by private firms in future, although for the moment the concession as regards capital expenditure may be largely ineffective; but it is the more important to direct attention to these questions first rather than to the selection of problems for immediate conjoint research, because of the trend in so many reports from the 'working parties' of the Board of Trade to advocate a compulsory levy for research. There is real danger that even a voluntary subscription to a research association may act as a sedative and induce a reluctant firm to think that it has done all that is necessary, and take no further steps to ensure that it is staffed and equipped to utilize the results of research as they are made available.

More effective liaison work may do something to decrease the danger, and hence the growing importance of the work of the information departments maintained by the individual research associations and centrally by the Department of Scientific and Industrial Research. Compulsory contributions are, however, likely to increase the danger, and for this reason alone experiment with the alternative type of organisation, the research foundation, might well be worth while.

That idea has received strong support in recent conferences; the Fulmer Research Institute, opened last July, is one of the first steps taken to fill a recognized gap in the organisation of research in Great Britain, and in welcoming this initiative, Sir Stafford Cripps, then President of the Board of Trade, expressed the hope that the Institute would be the forerunner of others on similar lines which might largely fill the gap altogether. At the Scottish Regional Conference of the Federation of British Industries in Glasgow last April, Prof. R. Hay suggested the establishment of a foundation for Scotland on Mellon Institute lines, and in view of Sir Edward Appleton's remarks at the Manchester Conference on "Research and the Smaller Firm", it would appear that concrete Government support may be forthcoming for particular proposals of that kind. While the organisation of research in Great Britain is still fluid, every opportunity should be utilized of making such experiments before too heavy a proportion of the nation's resources for research are committed to particular forms that may prove to be not the most desirable.

The importance of research organisation is well brought out in a recent survey of German research institutions by Col. L. E. Simon*. According to Col. Simon, German war research was defective in three respects. It failed to plan basic research with appropriate anticipation of future requirements for development—much time was wasted on stop-gap measures; it did not provide an adequate development echelon which was independent of self-interest; and intelligent communication between research units and the German army was lacking. For such reasons, in spite of the quality of much of their basic and technical research and the excellence of design, German research on war weapons was markedly inferior to that of Britain or the United States. Defective leadership and absence of effective means for technical co-ordination, coupled with poor development, in Col. Simon's view, probably reduced the effectiveness of German research and development by fifty to ninety per cent.

That verdict alone invites a closer scrutiny of the structure developed in Great Britain for war purposes, and particularly of what is usually described as 'operational research', with the view of seeing whether any features of the latter should be incorporated in our peace-time system. Before doing so, Col. Simon's observations on the institute as the fundamental unit in the organisation of research are worth noting. In view of the proposals made in Britain for development on such lines, it is of interest that Col. Simon commends the idea for trial in American industry, and he outlines with some care the factors to which its success in Germany is attributed. The institute should not be larger than one man can administer effectively through group leaders only one echelon above the research workers themselves, and in practice this means a staff not exceeding three hundred in all. The leader in an institute of this size should not tend to become an administrator instead of a scientific leader. Obviously, there are other questions of organisation, such as the relation of the institute to other research units and to industry, the universities or departments of State; but Col. Simon seems to think that such a unit has inherent possibilities of avoiding the danger which Sir Henry Dale emphasized and to which Mr. John Mills, lately director of publications at the Bell Telephone Laboratories, also directed attention in his recent book, "The Engineer in Society", that of diverting our ablest scientific minds from the creative work of research into administrative work which could be done by others less fertile and imaginative, even if they too require some appreciation of the scientific attitude.

For the rest, what Col. Simon notes about the conditions most conducive to creative research confirms what was emphasized in the Barlow Report on Scientific Staff and in other reports which have appeared in Britain and in the United States during recent years. To most of these considerations Government, the universities and industry now appear to be fully alive, and it is to be hoped that restrictions imposed by the economic crisis will not be allowed to endanger the situation. There is, in fact, at least some reason for concern at the apparent lack of appreciation on the part of the Government as to the importance of incentives for research workers, even if the threat is indirect rather than direct. Many of the general restrictions already imposed from quite other considerations have a detrimental effect on efficiency which, by engendering a feeling of frustration, tends to undermine incentives and destroy the atmosphere in which creative work is most fruitfully pursued.

One other factor noted by Col. Simon may also be mentioned—that of scientific intercourse and the exchange of ideas—and this stresses the value of the new intelligence group of the Department of Scientific and Industrial Research, some of the research stations of which may well be regarded as research units of the type mentioned above. Into the same category would fall a number of the research associations, such as the British Cotton Industry Research Association, which maintain a central institution; but we are here concerned with a factor which does not appear in Col. Simon's analysis. The units he describes are occupied essentially on fundamental research or the search for new knowledge of a broad or general character, and only to a lesser extent with technical or engineering research as he terms it.

The comments in the third report of the Select Committee on Estimates as well as the establishment of the Advisory Council on Scientific Policy warrant a hope that an inquiry will be held into the possible types of organisation for co-operative industrial research.

---

* German Research in World War II: an Analysis of the Conduct of Research. By Colonel Leslie E. Simon. Pp. x+218. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1947.) 24s. net.

There is a further matter relating to the expansion of the research association movement which requires consideration. A number of the research associations have already recognized that the utilization of the results of research by an industry depends on the presence within the industry of men able to appreciate the significance of these results and to apply them in practice. That has been repeatedly stressed in reports from the 'working parties'. The most effective way of strengthening an industry is by the recruitment of young men of wide educational background and of a scientific attitude of mind. The 'working party' for the lace industry in its recent report gave close attention to this question of recruitment and training, and pointed out that the presence of such men in the industry would assist it to make the best use of the results of research and also help to render fruitful the investigations carried out by individual firms.

No attempt was made in this report to indicate how such recruits should be introduced to the lace industry, and one aspect of the research association movement or the research institute which needs to be studied more closely is its success in supplying industry with men with a scientific training and research outlook, and in securing the interchange of staff. This, with such an industry as the lace industry, is just as important as securing close contact of the association or institute with the industry it primarily serves; one important factor in the success of the Institute of Paper Chemistry at Appleton, Wisconsin, is probably its location in a compact area of paper mills and paper-mill machinery manufacturers, and its association with Lawrence College, so that teaching and research are associated as in a university. Once this problem of the introduction to the industry, particularly at the managerial and administrative level, of men of a scientific outlook, qualified and competent to appreciate the contribution of science, is overcome, there will be little difficulty in formulating appropriate programmes or targets for research. But unless it is done, and the industry becomes thus qualified to interpret and apply, and even in some degree to direct research, there appears to be real danger that the measures contemplated by the lace industry 'working party' in regard to research and development may have only a passing effect, and fail to produce the sustained effort and the change of outlook that are imperative.

We have to remember that the traffic between science and industry must be in both directions, and the research association or the research institute, like the research department of an individual firm or of a Government department, must look not only to the manufacturing department or works, but also to the universities and other centres where the frontiers of knowledge are being continually advanced. The importance of this has indeed been strongly impressed on us by our war-time experience. Sir Edward Appleton referred in his lecture to the brilliant success of university men of science in solving war problems entirely remote from their peace-time interests, and to the way in which university conditions generally favoured the maintenance of the mental adventurousness and lively imagination so necessary for scientific progress. Possibly the regional research council might make an important contribution here.

The Interdepartmental Scientific Panel is clearly seeking to ensure that conditions in the future Scientific Civil Service of Britain encourage these same qualities, but in the meantime the brilliant success which has attended the close collaboration between scientific worker and Service man already noted has led to the suggestion that the same type of collaboration should be organised for the attack on peace-time objectives. The value of close collaboration between producer and user has long been recognized in some sections of industry, as is evident in the technical service to customers maintained by numerous progressive firms. In this dual flow of ideas there is a continuous improvement in the products of industry; and the value of contact between user and investigator and of all concerned in a research problem could scarcely be better put than by Dr. Price Russell in his lecture "The Organisation of Industrial Research" before the Industrial Research Committee of the Federation of British Industries.

The similarity between this and the basic idea behind 'operational research' is obvious, and Sir Robert Watson-Watt has made the pertinent remark that operational research is beginning to look very like real scientific management. Leaving for the moment the possible contribution 'operational research' may make to the still unsolved problem of the relationship between the administrator and the expert, and confining ourselves to the scientific and technical level, there should be noted the value, established in our war-time medical research, of a section composed of independent, full-time and fully mobile observers; and the conclusion that minority opinions should not be ignored even when counter to expected results. To both of these points Prof. W. C. Wilson has directed attention; but much careful thought will be required as to the means by which the first feature, which has something in common with the nuclear group described by Sir Percy Dunsheath, can be incorporated in our existing organisation.

In the main, however, those who, like Prof. J. D. Bernal, are anxious to see the technique of 'operational research' adopted in our peace-time structure, are thinking of doing so at a higher level, and with the view of seeing that Great Britain's limited resources in engineering and science are used in the most effective way possible, having regard not merely to the existing situation, but also to the way in which resources could be very considerably and rapidly increased. To some extent that is a matter of providing what Dr. R. P. Russell termed the political climate of research; but apart from what could be done at that level, it rests largely with scientific workers themselves to ensure that so far as organisation is concerned the channels of communication are adequate and effective, and that there is a free flow of workers and ideas between the universities, industry and the departments of State. New departures, such as the diversion suggested by Dr. Wansbrough-

Jones of young scientific men really interested in the social applications of science for a short time to 'operational research', may well assist. With adequate safeguards it might be an advantage to many to work for a year or so, say in their late twenties, for a Government department; to leave industrial laboratories to work on the scientific man-power side of their industries, and defence laboratories to work with the Services.

These are all tactical measures designed to increase mobility and, by facilitating the interchange of staff and ideas, to foster that cross-fertilization of minds which is so fruitful of real scientific advance. If such measures are to succeed, however, they must secure the cordial support and the careful and unceasing criticism of men of science themselves, individually and through their professional associations. They must be quick to note and to make representations against any developments which, by over-organising science, or, for example, hindering the vital freedom of the investigator to single out the right path to his objective in the complex situation existing on the frontier of knowledge, and to resist encroachment from the administrative side as to the methods to be adopted and/or the particular paths to be followed in the search for solutions of scientific problems. In his presidential address to the Royal Society Sir Robert Robinson indicated that this particular danger is now very slight. Even the selection of problems for investigation cannot be made wisely without the participation of the scientific investigator himself; and the most disturbing features in both Sir Edward Appleton's lecture and the report of the Select Committee on Estimates are the indications that in some departments of State all is not well in this respect, and that there is still failure to identify departmental problems suitable for scientific treatment, to see that these problems are passed to the appropriate research bodies for handling, and to interpret the incoming scientific material for the special departmental purposes.

It may be the function of the Advisory Committee on Scientific Policy to remedy defects in departmental organisation in due time; but no matter how efficient the organisation for research which is ultimately developed for the nation's purposes, in the sphere of Government itself, in the universities or in industry, no matter how well balanced the distribution of man-power between the different fields, or adequate the financial endowments and other material resources, the benefits the nation derives will depend ultimately both on the quality of the men of science engaged in the research and of those who, whether or not they are themselves men of science, are responsible for the administration. It is appropriate that at this present time the whole organisation and expenditure of the nation on research and development should be subject to the closest scrutiny, that the impact of restrictions on capital development should be examined, and that the possibilities of new types of organisation for research and new techniques for co-operation should be explored. There can be no more finality in the organisation than in the results of research.

MATHEMATICS OR PHYSICS?

Conduction of Heat in Solids

By Prof. H. S. Carslaw and J. C. Jaeger. Pp. viii+386. (Oxford: Clarendon Press; London: Oxford University Press, 1947.) 30s. net.

CARSLAW and Jaeger have produced an interesting book, different parts of which will meet the needs of mathematical physicists, experimental physicists, university teachers and design engineers. It is didactic rather than exploratory. In plan it owes much to Carslaw's "Introduction to the Mathematical Theory of the Conduction of Heat in Solids" which appeared in 1921; but the volume now under review differs so much from the earlier one that it must be considered as a new work rather than a revised version of the older one. It embodies many advances that have been made during the past twenty-five years, as can be seen from the numerous references to mathematical, physical and engineering publications, many of which have been published since 1921. The references also indicate that while attempting to give the book a pronounced mathematical flavour, the authors have also tried to make it useful to engineers and physicists. In addition, some essentially 'practical' topics are treated briefly in the text; of these some of the more interesting ones are: cooling fins, the conduction of heat in a thin wire heated by an electric current, automatic temperature control, heat regenerators and heat exchangers, the heating of a chain of radiating slabs, etc. No attempt has been made to treat these topics in great detail, but references are given to the relevant further literature.

The preparation of the book must have presented the authors with almost all the types of problem confronting those who write on branches of physics that lend themselves to detailed mathematical treatment. Should the subject be treated as a physical one, and the mathematical techniques of solution relegated to appendixes or to sections in smaller type? Should there be a discussion of fundamental principles, or should it be assumed that readers will be familiar with them? Should the book be written for research workers, or for teachers and students? There is no doubt that the authors were aware of these questions and that they decided to assume that the basic physical ideas were well known. Problems were grouped and discussed according to the mathematical techniques employed in solving them. For example, after an introductory chapter (1) dealing with the derivation of the equation of the conduction of heat, the appropriate general theory, boundary conditions, uniqueness of solutions, etc., there follows a sequence of chapters (2–9) in which are grouped problems that involve the flow of heat in an infinite and semi-infinite solid (2), solids bounded by two parallel planes (3), in a rod (4), in a rectangle (5), etc.

At this stage, the mathematical technique of the Laplace transform is introduced (11). This chapter contains an outline of the history of the development of the transform, of its fundamental mathematical properties, and of its application to problems involving the linear flow of heat. The remaining chapters (12–15) deal primarily with the application of the transform to problems more complicated than those discussed earlier in the book. The authors point out that the Laplace transform could have been introduced earlier in the text, and that such an early introduction would have simplified much of the previous chapters. They felt, however, that the juxtaposition of the classical technique and the more modern one should be very helpful, and the reviewer agrees with them wholeheartedly. Six valuable appendixes conclude the text.

The book would have been more satisfying had more space been devoted to brief critical accounts of physical principles and definitions. For example, the orders of magnitude of the variation of conductivity and specific heat with temperature might have been discussed and, where known, the results of taking these variations into account might have been compared with the result of assuming these quantities to be constants. Or again, the note on the effect of turbulence on the coefficient of outer conductivity might have been amplified.

The authors have written on a difficult subject. They have formulated their plan with care and have kept to it. Others, including the reviewer, might have preferred a more physical approach without the sacrifice of any of the mathematical ingredients of the publication, but this is purely a matter of opinion. Carslaw and Jaeger are to be congratulated upon this addition to the literature of the conduction of heat in solids, and note should be taken of the compliment paid by Prof. Carslaw to his junior colleague, Dr. Jaeger, when he says in the preface "He is most certainly its principal author".

This review would not be complete without a special note of praise for the printing and binding. Those whose work involves a close scrutiny of scientific texts are indebted to the Oxford University Press for the continuation of its high standards even in times of great difficulty. L. ROSENHEAD

THE NEUROTIC PERSONALITY

Dimensions of Personality

By Dr. H. J. Eysenck. A Record of Research carried out in collaboration with Dr. H. T. Himmelweit, Dr. W. Linford Rees, and with the help of Dr. M. Desai, W. D. Furneaux, H. Halstead, Dr. O. Marum, M. McKinlay, A. Petrie and P. M. Yap. Pp. xi + 308. (London: Kegan Paul and Co., Ltd., 1947.) 25*s*. net.

THIS book is based upon research carried out by a team of psychologists working at the Mill Hill War Emergency Hospital. The object of their investigations was to discover the relationship of various traits of personality to 'neuroticism'. The experiments were performed on a group of patients, numbering seven hundred, suffering from reactive types of mental illness. The statistical method was used, and careful correlations are given for the various traits.

The authors state that two main facts emerge from their study. First, there is a general factor, 'neuroticism', shown by signs of a badly organised personality, poor muscular tone, pre-service evidence of abnormality, abnormal parents and unsatisfactory home-life. Secondly, a bipolar factor with affective type of symptoms (anxiety, depression, obsessional tendencies, etc.) at one end and hysterical type (conversion symptoms, sex anomalies, low intelligence, bad work history, hypochrondriasis, etc.) at the other.

A number of studies were made upon physique and constitution, such as body build, autonomic activity, dark vision, choline esterase secretion and exercise response. The authors claim significant differences between the two groups. Other studies were made upon neurotics and non-neurotics with regard to intelligence, accuracy of work, level of aspiration and so on. These tests are claimed to differentiate dysthymics from hysterics and normals from neurotics.

Tests were also made upon various types of suggestibility and the relation of them to hysteria. The authors believe that there is no evidence that hysterics are more suggestible than other neurotics. They found, however, that suggestible patients were made more so by narcotics, whereas non-suggestible ones remained unaffected. In the experiments made upon appreciation and expression it was found that neurotics were more reactive to colour, but there was no difference between the hysteric and the dysthymic.

These tests may arouse some readers to complain that the mind is so fractionated in such a study that nothing much is proved. Prof. Aubrey Lewis, in the brief foreword, answers this objection that the methods are 'atomistic', and points out that it is an attempt at "the analysis, by reliable statistical techniques, of experimental and clinical data, so that measurement may be possible and a sight obtained of the promised land where mental organisation will be as well understood as the physical organisation of human beings is".

This research is interesting, and the frequent quotations show a wide knowledge of the literature. A few show an unnecessary desire to quote from other Maudsley colleagues, as, for example, that on page 51: "A person's constitution may render him liable to breakdown at the slightest provocation; on the other hand, a person of first-class constitution may finally break down when the stress is too great." This is such a psychiatric commonplace that surely it has been stated many times before Slater in 1944. These, however, are minor blemishes and the book as a whole is valuable.

The format is neat, the paper good and the printing clear. It is written as easily as such a subject allows. There is a useful summary of the findings at the end of each chapter and many diagrams clarify the text. There is a long bibliography of 24 pages and an excellent index. CLIFFORD ALLEN

"CUSHNY'S PHARMACOLOGY"

Pharmacology and Therapeutics

Originally written by Prof. Arthur R. Cushny. Thirteenth edition, thoroughly revised by Prof. Arthur Grollman and Dr. Donald Slaughter. Pp. 868. (London: J. and A. Churchill, Ltd., 1947.) 45*s*.

WHEN Cushny's text-book first appeared in 1899, it was recognized as being "the first severely critical, rigorously scientific general text-book to be written in English by an experimental pharmacologist". It helped to put the science of pharmacology on secure foundations by eliminating traditional lore and concentrating attention on proved facts. It became the standard text-book in English on both sides of the Atlantic, and Cushny himself was responsible for eight editions. After his death in 1926, four more editions were prepared jointly by Prof. J. A. Gunn of the University of Oxford and Prof. C. W. Edmunds of the University of Michigan. The thirteenth edition, which has recently appeared, is a purely American production. Most of the work of revision has been done by Prof. Arthur Grollman, who is professor of both medicine and pharmacology at Southwestern Medical College, Dallas, Texas, and is well known for his work on the circulation and on the adrenals. The section dealing with depressants of the central nervous system has been revised by Dr. Donald Slaughter.

The revision has been thorough and must have been a vast labour. Pharmacology is advancing rapidly and nearly all the new advances have been included. It is unfortunate that new revisions of both the British and United States Pharmacopœias are appearing too late to influence this edition, but the pharmacological information is well up to date. Among the newer drugs which appear are streptomycin, folic acid, "Paludrine", tridione, *B.A.L.*, *D.D.T.* and *D.F.P.* (these initials mean as much to the pharmacologist as the full chemical names). There are many references to work published in 1946, but the material must have gone to the printers fairly early in the year or the formula of synthetic folic acid would undoubtedly have been included. In spite of many changes, the general arrangement has not been altered and the critical spirit has been maintained; there is rather more emphasis on practical applications and rather less emphasis on academic experiments with isolated organs.

Text-books almost always show a certain amount of national bias, and it is interesting, and perhaps a little sad, that this one now shows some slight signs of American bias. The section on anthracene purgatives was apparently written in ignorance of Straub's work on senna. Benadryl and pyribenzamine are mentioned, but not antergan and neoantergan. Benzestrol is included, but not dienœstrol. Lanatoside *C* takes the place of digoxin. Most of these differences are superficial and merely serve to illustrate the fact that new discoveries may be applied in slightly different ways in different countries. There can be no doubt that this new edition of Cushny's book maintains a high standard and will be an invaluable source of information both for students and their teachers. Few students will read it all but many will keep it for reference, and it can be warmly recommended for this purpose. J. H. Gaddum

POPULATION OF THE SOVIET UNION

The Population of the Soviet Union

History and Prospects. By Frank Lorimer. (League of Nations Publications. II. Economic and Financial. 1946. II. A.3.) Pp. xiv + 289. (Geneva: League of Nations; London: George Allen and Unwin, Ltd., 1946.) 15*s*. net.

KNOWLEDGE concerning the U.S.S.R., apart from political opinions of various colours, has been hard to get. We have had invaluable essays, notably by Sir John Maynard and Sir Bernard Parcs, but there has long been a serious need of more information than such reference books as the "Statesman's Year-Book" could find space for. This gives a special value to the publication under review. Dr. Lorimer studies and provides not only the available facts of population and employment, but also, by detailed comparison of data for 1926 and 1939, reviews the dynamics of population changes and movements during this period of vital change.

A Russian population roughly estimated in 1724 as 17,900,000 reached a total of 58,629,000 in 1859, by which year Russians in the Asiatic part had reached 3,424,000. In 1897 the figure was 94,331,000 Russians (6,947,000 in the Asiatic part), to which must be added more than 31,000,000 non-Russians, making in all 125,640,000. For 1914 the total is estimated at 142,389,000, but the terrible years 1917–23 reduced it to 136,102,000, since when it was on the up-grade until the recent War. It passed its 1917 figure in 1926–27, with 11,802,382 east of the Urals. In the 1939 area of the U.S.S.R. there were at the end of that year 173,788,000. We thus have a continuation of a large percentage increase. Projections of population are given which show that war losses in numbers should be made up before 1950, and the 200,000,000 mark passed before 1960. As the population of North-western and Central Europe is expected to decline after 1950, it is estimated that the U.S.S.R. will equal North-western and Central Europe in population by 1970, and is more likely to go on increasing thereafter. The age composition of the population is strikingly different from that obtaining in North-western and Central Europe (figures are given in percentages).

	Young people	Males 20–44	Males 45–64	Females 20–44	Females 45–64	Old people
U.S.S.R., 1939–40	45	18	6	20	7	4
N.W. and Central Europe	32	19	10	19	12	9
Estimated, U.S.S.R., 1970	35	20	9	20	10	6
Estimated, N.W. and Central Europe, 1970	21	18	14	18	14	15

Though it is anticipated that the expectation of life will increase, this extract from the tables shows that the proportion of young people is likely to remain far higher in the U.S.S.R., and the proportion of old people will be much less than elsewhere in Europe.

City growth is as marked in the U.S.S.R. as elsewhere. Moscow doubled and Leningrad nearly doubled during 1926–39, reaching more than 4 and 3 millions respectively. In 1926 Kiev had 513,637; by 1939 nine towns besides Moscow and Leningrad had topped the half-million. In 1926 about thirty other towns had 100,000 or more; in 1939 the number was 71. Figures from German sources for the period of the Hitlerian invasion naturally show enormous reductions, especially for Ukrainian towns.

The amount of sown land per head of the population not only kept pace with population increase in nearly all regions except Belorussia, Karelia, Murmansk and Azerbaydzhan, but actually increased, the average for the U.S.S.R. rising from 0·936 to 1·195 hectares, the increase in the Lower Volga and Don regions and Kazakhstan being outstanding.

The net reproductive-rate, as usual, is far higher in rural than in urban areas, and as the average for the whole of the U.S.S.R. in 1938 was estimated at 1·54, the rural birth-rate is very high indeed. In rural areas women between twenty and thirty-nine are responsible for nine-tenths of the births. In urban areas the number of births to women of less than twenty is slightly larger; those to women of forty and more are much less. The birth-rate in 1938 was as high as 38·3 per thousand and the death-rate was 17·8.

There are 22 maps, 103 tables and 31 figures, and they deal with occupations and industrialization as well as with vital statistics of many kinds. Readers will find the statements of fact invaluable, and perhaps scarcely need to be warned that projections suggesting future conditions are subject to a good many reserves. H. J. Fleure

THE GEOLOGICAL SURVEY OF INDIA, 1846 TO 1947

By Sir CYRIL S. FOX

Formerly Director, Geological Survey of India

NOW that the Empire of India has ceased to exist as a British possession and the control of the services in Hindustan and Pakistan has passed from Whitehall, the records of many British-organised services will be reviewed and then perhaps forgotten. I had attempted to tell the story of the Geological Survey of India ten years ago in my presidential address to the Mining and Geological Institute of India (*Trans. Min. and Geol. Inst. India*, **31**; 1936). It was evident to me then that the beginnings of the Geological Survey of India were not correctly known, and certainly not as represented in the record by Sir Clements R. Markham ("Memoirs of Indian Surveys", p. 216; 1878), nor as given by Sir Thomas Holland in his "Indian Geological Terminology" (*Mem. Geol. Surv. India*, **51**, Part 1; 1926). I began a search for information in India, first among the files of the Geological Survey of India, then in the Record Office in the Secretariat of the Government of Bengal, and finally, on my return to Britain last summer, in the record room at the India Office, Whitehall. The correspondence relating to the engagement of David Hiram Williams and, eventually, after his death, to that of Thomas Oldham and his re-engagement after five years service, show that Oldham was recruited as "successor to Williams", and that, even at the time of his re-engagement by the Honourable Court of Directors of the East India Company, Oldham was addressed as "Geological Surveyor". These facts are quite plain in the dispatches to India and Bengal from London, and may be seen in the Commonwealth Relations Office, King Charles Street, London, S.W.1, through the Superintendent of Records.

Already in 1835 the subject of India's coal supplies for the steamers for inland navigation was under consideration, and this led to the establishment of a Coal Committee in 1836, with Dr. John McClelland (Medical Services) as secretary. The reports of the (Indian) Coal Committee of 1838 and 1846 are well known, but it has so far been practically unknown that John McClelland had conducted correspondence with Charles Lyell and with R. I. Murchison on the question of employing trained geologists in India. The earliest letter I have seen is dated February 10, 1841, from McClelland to Lyell, expressing a desire for a scientific examination of the coalfields of India; the second is dated September 22, 1842, from Murchison to McClelland, in which reference is made to the appointment of Sir H. De la Beche to the post of "geologist of the Ordnance Survey"; and the third is dated May 10, 1843, from Lyell to McClelland, also referring to the establishment of geological surveys in Canada, etc. Then there is a letter, dated August 16, 1843, from the Coal Committee to the Secretary to the Government of Bengal, enclosing the correspondence with Lyell and Murchison, and asking that they might be consulted on this matter of a proper geological survey of India. This was followed by a letter ("Steam", No. 2091, dated September 4, 1843) from the Government of Bengal to the Government of India, with a strong recommendation from His Honour, the Deputy Governor of Bengal. The Government of India, in turn, wrote the following letter:

Home Department
Marine.
No. 13 of 1843.

To
The Hon'ble the Court of Directors
of the East India Company.

Hon'ble Sirs,

We have the honor to submit the accompanying communication from the Government of Bengal respecting the best means of ascertaining, with precision, the hitherto undeveloped resources of the country in the production of coal.

The papers which we transmit will explain to your Hon'ble Court the grounds on which the Hon'ble the Deputy Governor urges the expediency of adopting a system of scientific inquiry both with the view of securing success to such attempts as are made by Govt. and of promoting confidence among private speculators to embark in undertakings for obtaining coal, and in expressing our concurrence in the views and recommendations of His Honor, we beg to request that the selection of the Geologist to be sent out by your Hon'ble Court, may be left to Mr. Murchison, the President of the Geological Society in London.

We have, etc.

Fort William,
The 14th October, 1843.

There then followed a search in England for a suitable geologist to be sent out to India to begin the Geological Survey, and it was not until December 1845 that the following letter was dispatched from London by the Honourable Court of Directors of the East India Company:

Marine Department.
No. 8 of 1845.

Our Governor-General of India in Council.

Para. 1. With reference to your letter No. 13 dated the 14th October, 1843, we have to inform you that we have engaged Mr. D. H. Williams to proceed to India for the purpose of making a Geological Survey of those districts in which Coal Fields are situated, with the view of obtaining accurate information respecting the resources possessed by that country for the production of Coal and determining in what manner they may be best turned to account.

2. Mr. Williams has been strongly recommended to us by Sir Henry De la Beche, Director General of the Geological Survey of the United Kingdom under whom Mr. Williams has been for several years employed. Sir Henry informs us that he has surveyed many of the Coalfields in Wales and in the West of England and has executed very valuable maps and sections relating to them. He also represents him as having been in early life engaged in the working of Collieries and as being perfectly qualified to examine the Coal Districts of India, either geologically, or practically as well as to superintend Coal works.

3. These high testimonials leave no doubt of the fitness of Mr. Williams for the important duty which it is proposed to confide to him, and we trust that his labours will have the effect of ensuring success to such mining operations as Government may think proper to undertake and of encouraging private speculators to embark in similar attempts.

4. Mr. Williams left England with the mail of the 20th of the present month (Decr.) and will proceed to Calcutta to place himself under the orders of your Govt. The period of his engagement is limited to five years. He is bound to serve in any part of the East India Company's Territories to which you may direct him.

5. We have agreed to allow him a salary of £800 a year to commence from the date of his arrival in India exclusive of such travelling allowances as you may think reasonable; and we have also granted him £200 in aid for

his outfit and passage to India, and we have guaranteed him the like sum for his return to this country on the expiration of his period of service. He has also been furnished with a set of Instruments such as he is likely to require in India, in order that he may not be prevented from entering immediately on his duties. These instruments, a list of which is transmitted, are similar to those used in the Geological Survey of Great Britain and have been selected by Sir Henry De la Beche.

6. One of the parts of the Deed of Covenant entered into by Mr. Williams is forwarded in the packet for your information and guidance.

We are, etc.

London,
23rd Decr., 1845.

David Hiram Williams arrived in Calcutta on February 4, but did not report for duty, by letter, until next day, February 5, 1846. He was instructed by the Government of India (letter No. 134, Home Dept., Marine, dated February 7, 1846) to place himself at the disposal of the Government of Bengal, and by this Government posted to the Raniganj area. Williams' first field report, from camp at Raniganj, is dated March 31, 1846, and his first progress report, from Spence's Hotel, Calcutta, is dated August 10, 1846. From this report it is evident that Williams had noted: par. 4, the Coal Measures resting directly on the crystalline rocks; par. 7, two groups of coal seams—one with ten seams of coal around Raniganj and the other with fourteen seams of coal near Taldanga near the Barakar River; par. 8, coal near Induhghur (Jharia town), four miles south of the Fitcoory bungalow (ruins near Dhanbad at the Grand Trunk Road—he thus discovered the Jharia coalfield); par. 11, the importance of railway communication; and in a later field report, dated May 3, 1847, he records that the coal near Taldanga was of caking (coking) quality. His last known report is dated December 9, 1847. Williams had planned a series of investigations up the Damodar valley and had secured geological assistants—Mr. Haddon and Mr. Jones—when he contracted jungle fever and died in Hazaribagh in the house of Dr. Callum on November 15, 1848. And, while R. G. Haddon was reporting this sad affair and assuming charge of the Geological Survey at Hazaribagh on November 15, 1848, the body of J. R. Jones, the other assistant, was brought in in a palki. When Williams' death was reported to the Honourable Court of Directors in London in a letter dated January 31, 1849, they replied (letter No. 24, Marine Dept., dated Nov. 28, 1849) to "Our Governor of the Presidency of Fort William in Bengal" complaining of delays in the transmission of reports and as not having news of Williams' death until the autumn of 1849. They record their appreciation of the work done by Williams and propose to publish his reports, and desire McClelland to continue the work, while they add that:

> Para. 6. We propose to take immediate steps for securing the services of a suitable successor to Mr. Williams.

and ending "We are your loving friends . . . etc.".

Their next letter (No. 27 of 1850, Marine Dept., Dec. 11) to "Our Governor General of India in Council" includes

> "We desire that the earliest attention of the Geological Surveyor (Professor Oldham) whom we have lately appointed, and who will proceed to India this month, be directed to the subject."

The subject was the introduction of railways in various areas such as those to which Williams had directed attention. Then their further letter (Marine Dept., No. 9, March 5, 1851) to "Our Governor of the Presidency of Fort William in Bengal" followed with the counterpart of the covenant entered into by Prof. Oldham,

> ". . . lately attached to the Irish Branch of the Geological Survey of the United Kingdom whom we have approved to the situation of Geologist, in succession to the late Mr. D. H. Williams . . ."

In the above letter reference is made to their letter No. 24 of November 28, 1849, showing they had chosen "a suitable successor to Mr. Williams" as early as possible. Previous to Oldham's arrival in India (March 5, 1851), McClelland had carried on the duties which Williams had begun, and McClelland submitted the annual "Report of the Geological Survey of India for 1848–49". He had designated himself as 'officiating superintendent', Geological Survey, and had asked (letter dated March 23, 1850) to be relieved of his geological duties. The Department was therefore (letter dated April 1, 1850) temporarily placed under the charge of the deputy surveyor general, Captain Thuiller, R.E., from April 30, 1850, who addressed Mr. R. G. Haddon as assistant geological superintendent. Thus when Prof. T. Oldham arrived, he was in direct touch with the Surveyor General of India, but he was addressed as Geological Surveyor by the Government of India (letter No. 290, Home Dept., of March 21, 1851, from W. Grey, Esq., Under-Secretary) and informed that his services had been placed at the disposal of the Government of Bengal.

No. 189 dated Fort William, the 24th March, 1851.

From
The Secretary to the Government of Bengal
To
Professor T. Oldham.

Sir,

I am directed by the Deputy Governor of Bengal to transmit herewith, for your information, the accompanying copy of a letter from the Under-Secretary to the Government of India, in the Home Department, No. 291 dated the 21st instant, and to request you to proceed to the Sylhet Hills, with the view of prosecuting your researches there until the season will permit of your examining the Valley of the Damoodah. You will address your reports to this office.

2. At the time of the death of Mr. Williams the Establishment of your office was as following:—

Mr. Haddon	Rs350
Mr. Jones	Rs350
A sub. asst. surgeon	Rs100
A writer and interpreter	Rs50
	Rs850

3. Before Dr. McClelland made overcharge of the office the Establishment was as follows:—

Mr. Haddon	Rs350
Mr. Theobald	Rs100
Mr. Gomes	Rs100
	Rs550

The persons still borne upon your establishment are:—

Mr. Haddon	Rs350
Mr. Gomes	Rs100
	Rs450

4. Mr. Haddon and Mr. Gomes are at present on detailed duty at Purnear. But on your intimating to His Honor that their services will be required by you in your

researches in the Sylhet Hills, they will be directed to join at Sylhet, or Cherra forthwith.

5. You are requested to report upon the establishment you may think it necessary to employ.

I have the honor, etc.,
W. Grant,
Secretary to the Govt. of Bengal.

So Prof. Thomas Oldham entered upon his duties as 'geological surveyor' in succession to Mr. D. H. Williams, and when his period of five years expired and his services were secured by his re-engagement for a further period of five years, the Honourable Court of Directors of the East India Company wrote as follows (letter, India Public Dept., No. 16 of March 5, 1856):

"· · ·

Para. 2. The duties of the Geological Surveyor have been greatly enlarged since Mr. Oldham assumed charge of the office and the establishment which he has to control has been likewise increased owing to the simultaneous prosecution of geological researches in different parts of the country. In consideration, therefore, of the greater labor and responsibility thus attaching to the office, and of the experience which Mr. Oldham has now acquired, we sanction the increase of his salary from the present rate of Rs888 to Rs1,100 per mensem.

Para. 3. We observe with some surprise that the President in Council, as one of the reasons for the increase of Mr. Oldham's salary states that he is paid little more than his assistants. . . .

Para. 4. We take this opportunity of observing that we have not received so regularly as we would desire, reports of the progress of Mr. Oldham's labors. We are apprehensive that the operations of the Department may not have been carried out in a systematic and regular plan. We think it desirable that you should direct your attention to the importance of giving such a character to the work on which Mr. Oldham is engaged, as the only means of rending his employment personally useful and we desire that, in communicating to him his re-engagement you call on him to submit a general scheme in which his future investigations should be carried on, and that when a plan of observations shall have received your sanction, it should be adhered to with as little deviation as possible. We desire a full report of his past labors and any maps he may have made be sent to us.

We are your affectionate friends,

· · ·"

I think that the correspondence I have quoted and referred to will make it very evident that India owes a great debt to Dr. John McClelland in initiating a Geological Survey and very much more to the Honourable Court of Directors of the East India Company in providing the personnel and in taking a close interest in the establishment of the department on sound lines, also to the Government of Bengal for the consideration they showed Oldham after the losses suffered by the deaths of Williams, Jones and, soon after, Haddon, from the effects of jungle fever. It may be, and has been, claimed that in the century completed by the Geological Survey of India on February 5, 1946, the whole of India should have been thoroughly examined and mapped. That this could have been done only by having a large staff and elaborate equipment will be seen from the fact that an experienced geologist can map about 500 square miles a season on an average. There have been, roughly, a hundred and twenty geologists with average field service of barely eight years each, so that the area that could have been mapped is about 500,000 square miles, which was barely a third of the Indian Empire. This does not allow for all the detailed work that has been carried out, and in spite of which the Geological Survey of India had examined practically the entire region of India, part of Burma and some adjacent countries, by the end of its centenary year 1946. Instead of a cadre of thirty to forty officers, the department was already in need of three hundred to four hundred officers at the outbreak of war in 1939 to conduct a thorough economic exploration and exploitation on the lines which Mr. David Hiram Williams was to follow, to say nothing of the important branch of water-supply and of questions of engineering geology.

THE BRITISH-KENYA MIOCENE EXPEDITION, 1947

ONE of the discussions at the Pan-African Congress on Prehistory, which took place at Nairobi in January of this year, was concerned with the fossil remains of Miocene apes which have been found in Kenya during recent years. Some of the delegates to the Congress also visited Rusinga Island (near the Kavirondo Gulf of Lake Victoria) where Early Miocene deposits particularly rich in such fossils had been discovered by Dr. L. S. B. Leakey and Dr. D. G. MacInnes of the Coryndon Museum, Nairobi. It was here that Dr. Leakey found in 1942 a practically complete mandible of the extinct anthropoid ape, *Proconsul*, originally described on the basis of portions of the jaws and teeth discovered at Koru by Dr. A. T. Hopwood.

The opportunities provided by the Pan-African Congress served to focus attention on the great importance of these Miocene sites, and as a result a British-Kenya Expedition to Rusinga Island was organised with the aid of a grant of £1,500 from the Royal Society supplemented by a gift of £250 from the Aga Khan. The expedition was led by Dr. Leakey as field director, with the assistance of Dr. MacInnes as palæontologist. A very detailed geological study of the Miocene beds in the island was included in the programme, in order to supplement the preliminary survey carried out by Dr. P. E. Kent in 1934–35 (see *Quart. J. Geol. Soc.*, **100**, 85; 1944). The geological work of the expedition was supervised by Dr. R. Shackleton, of the Imperial College of Science and Technology, London. While the expedition concentrated its attention on Rusinga Island, brief reconnaissance work was also carried out at Mwafangano, Karungu, and on the Uyoma mainland, and a few days were spent on the Miocene site at Songhor. Work was begun on July 10 and the season ended on November 13.

The principal aim of the Expedition was to obtain further remains of the Early Miocene fossil Hominoidea, and to collect the associated fossil fauna and flora in as much detail as possible for a correlated study of the contemporary environment. Full reports of the season's work will take some time to prepare, but it is now possible to say that the results have been eminently satisfactory. More than 1,300 fossils have been collected, and these include about thirty more specimens of the fossil Hominoidea (probably representing five different genera). Among the more important hominoid discoveries are the palate and mandible of a medium-sized ape (regarded provisionally as *Xenopithecus*), a part of a mandible (including the symphysis) of an ape considerably larger than *Proconsul*, the left half of a palate of an infant Hominoid probably referable to *Proconsul*, and some fragments of limb bones.

The last are likely to be particularly instructive since almost nothing is yet known of the skeletal anatomy of Miocene apes or of their limb proportions. There are already available from Miocene deposits in Kenya an almost complete femur of a large primate (presumably *Proconsul*), as well as the shaft of the humerus, a portion of the clavicle, and some tarsal bones. These are in course of examination in the Department of Anatomy at Oxford; if their reference to *Proconsul* is correct, they indicate that, while from the size of its jaws and teeth it is apparent that this fossil ape approximated to the chimpanzee in its general size, it was of much lighter build and a much more active and agile creature. The femur shows a remarkable resemblance to the femur discovered at Eppelsheim at the beginning of the last century and commonly regarded as the remains of a large gibbon-like ape of early Pliocene date. The humerus, also, is similar to that of the Miocene ape, *Dryopithecus fontani*, described by Lartet in 1856.

The associated fossils collected at Rusinga during the expedition include (1) the greater part of the skeleton of a member of the Rhinocerotidæ (allied to, but distinct from, *Aceratherium*), (2) a considerable quantity of remains of a giant Hyracoid, probably referable to *Pliohyrax*, (3) a number of specimens of *Myohyrax*, including a nearly complete skull, (4) very numerous fossil rodent remains, (5) remains of carnivores, anthracotheres, chalicotheres, insectivores and Suidæ, (6) numerous plant remains, (7) numerous fossil fish, (8) a large collection of myriapods and gastropods, and some pelecypods. As soon as this rich collection has been sorted out and catalogued, the several groups which it contains will be allocated to different laboratories for detailed study.

That so much important fossil material has been collected in one season's work is a tribute both to the richness of the Miocene deposits on Rusinga Island and to the energy and skill of the members of the expedition. The discovery of remains of Early Miocene apes of a generalized kind is of particular significance, since they are likely to throw important light on the evolutionary radiations of the whole group of the Hominoidea. For this reason, it is earnestly to be hoped that funds may be forthcoming for another season's work in 1948. There is a reasonable certainty that this would procure still more limb bone material of Miocene Hominoids; but it is also of the greatest importance to search for parts of the skull (in addition to the mandible and maxilla, of which some remains have already been obtained).

Another consideration arises from the outstanding discoveries in Kenya of Dr. Leakey and his associates, not only of primitive fossil apes but also, in the field of archæology, of early remains of man and his palæolithic cultures. This is, that they are now attracting the attention of prehistorians and palæontologists in other countries. It has recently been reported in the Press that a well-equipped expedition from the University of California is now on its way to East Africa to operate on sites such as those discovered by British investigators, and no doubt other expeditions of a similar kind may be expected in the future. I would therefore urge the desirability of establishing in East Africa an Archæological Survey, with an adequate staff and appropriate financial resources, to organise facilities for, and to co-ordinate the activities of, expeditions into this territory. It is much to be hoped that serious attention will be given to this urgent problem.

W. E. LE GROS CLARK

PHYSICO-CHEMICAL ASPECTS OF CHEMICAL CARCINOGENS

By WILLIAM ANDERSON

Research Department, Glasgow Royal Cancer Hospital

Experimental

SINCE it was first demonstrated that cancer could be induced by a pure chemical compound, the mode of action of chemical carcinogens has been studied from many different points of view and numerous theories have been evolved from the results of controlled experiments on these substances[1,2]. The following observations present yet another aspect from which the problem may be considered.

A large number of the carcinogenic compounds possess no functional group in their molecules and it is therefore difficult to understand how they can bring about the malignant change in a cell by a purely chemical interaction. Furthermore, although the metabolites of many of the substances are derivatives containing hydroxyl groups, the evidence available indicates that hydroxylation causes a diminution of the carcinogenicity of the parent substances[3]. Consequently, some physicochemical explanation of the mode of action of carcinogens was sought. The idea occurred that carcinogenesis by chemical compounds, in particular the polycyclic aromatic hydrocarbons, might have its origin in a chemiluminescence accompanying the hydroxylation of the substances *in vivo*. This concept seemed feasible since it is known that electromagnetic radiations can bring about malignant transformation, and on the other hand, that oxidation of certain organic compounds is accompanied by the emission of radiation. It is also interesting to note that, simultaneously, other investigators have been led to suggest similar ideas[4,5]. It was decided in the first instance to study the reactions of the polycyclic aromatic hydrocarbons under the influence of hydroxylating agents.

Among the reactions accompanied by chemiluminescence described by Trautz[6] are oxidations with chlorine or bromine water of anthracene, phenanthrene and chrysene dissolved in hot alcohol saturated with potassium hydroxide. These reactions were repeated substituting various other hydrocarbons for anthracene, etc., and in each case chemiluminescence was observed. The compounds tested were: naphthacene, 1 : 2 : 5 : 6-dibenzanthracene, 9 : 10-dimethyl-1 : 2-benzanthracene, 20-methylcholanthrene, and 3 : 4-benzpyrene. The luminescence was momentary, due to the fact that an aqueous medium was added to a solution of the substance in alcohol whereby the material was thrown out of solution. The possibility that the radiation might be a crystalloluminescence was not borne out by control precipitation of the substances with water alone. It is likely that these oxidations were due to the formation of hypochlorite or hypobromite, since chemiluminescence could also be produced by adding an aqueous solution of sodium hypochlorite to the substances dissolved in alcohol.

The next reagent used was perbenzoic acid in chloroform solution, since Eckhardt[7] has described reactions between this hydroxylating agent and several hydrocarbons. Attempts to produce chemiluminescence with 3 : 4-benzpyrene using this reagent proved unsuccessful, but when the perbenzoic acid solution was added to a concentrated solution of 20-methylcholanthrene in chloroform, both solutions being heated to 50° C., a chemiluminescence lasting for three seconds was observed. A similar result was obtained from anthracene, when the luminescence persisted for thirty seconds. When further attempts to produce chemiluminescence with 3 : 4-benzpyrene and 9 : 10-dimethyl-1 : 2-benzanthracene failed, investigations using this reagent were stopped, since the technique was proving costly in hydrocarbons. A possible explanation of the fact that chemiluminescence was observed with anthracene and methylcholanthrene but not with the other hydrocarbons is to be found in Eckhardt's observations, which show that the rates of oxidation of methylcholanthrene and anthracene are the two fastest among those of the numerous compounds which he studied.

Various attempts had been made to produce chemiluminescence using hydrogen peroxide as the oxidizing agent, since it has been suggested[8] that the hydroxylation of hydrocarbons which occurs *in vivo* operates through a hydrogen peroxide system. These attempts were fruitless until the Milas[9] reagents were used, in which the hydrogen peroxide is incorporated in tertiary butyl alcohol and osmium tetroxide is employed as catalyst. With these reagents chemiluminescence has been so far observed with the following hydrocarbons: naphthalene; anthracene, phenanthrene, naphthacene, chrysene, 3 : 4-benzpyrene, 9 : 10-dimethyl-1 : 2-benzanthracene, and 20-methylcholanthrene. To observe these phenomena, the following technique was used: a solution of the substance was made in the (6 per cent) hydrogen peroxide–tertiary butyl alcohol reagent[9] by warming the solvent with the substance and filtering to remove the undissolved excess. To 5 ml. of this solution was added 0·5 ml. of a 0·5 per cent solution of osmium tetroxide in tertiary butyl alcohol. The radiation emitted was observed in a completely dark room, the observer having accustomed himself to the darkness for 15–20 min. prior to making the observation.

In contrast to the reactions with chlorine and bromine water described above, no precipitation occurs here and the chemiluminescence persists for 15–80 sec., so that the reactions are suited to controlled experiment. The experiments with the other reagents had been conducted at raised temperatures (50°–80° C.), but with the Milas reagents radiation has been observed at 37° C. with certain of the hydrocarbons. Several of these oxidations have been studied more fully, and fluorescence spectra of the reaction products together with solubility in alkali indicate the presence of hydroxylated derivatives. Further details of these investigations will be published elsewhere.

The question then arose as to whether the other chemical structures which fall within the classification 'chemical carcinogens' would emit radiation in similar reactions. Metabolism studies show that 2-acetylaminofluorene undergoes hydroxylation in the rat[10]; and although investigations on the azo-dyes suggest that the main metabolic changes which occur are other than hydroxylation, it is perhaps significant that Stevenson, Dobriner and Rhoads[11] isolated *p*-aminophenol from rats dosed with Butter Yellow (*p*-dimethylaminoazobenzene), indicating hydroxylation at some stage in the metabolism. Chemiluminescence was observed using Milas reagents with 2-amino- and 2-acetylaminofluorene, and with Butter Yellow, the N-monomethyl compound, the free base, and *p'*-methyl-N : N-dimethyl-*p*-aminoazobenzene. Tests on other structures showed that radiation is emitted during the reactions with *p*-dimethylaminostilbene and 'styryl 430' [2, (*p*-amino styryl) 6, (*p*-acetylamino benzoylamino)-quinoline methoacetate] and with 3 : 4 : 5 : 6-dibenzcarbazole and its N-methyl and N-ethyl derivatives.

The spectra of the radiations from the reactions have not yet been recorded, since the light is of very low luminosity under the experimental conditions obtaining, but work in this direction is in progress. The radiation so far observed has been in each case a weak green or greenish-white light, with the intensity varying from substance to substance and with the temperature of the reaction mixture. It is possible to grade the intensity of the radiation from a given reaction as weak, medium bright, or bright; but these data have not been recorded here, since obviously they would bear little relation to the intensity of the radiation from a similar reaction occurring *in vivo* where the reactions are of a heterogeneous nature. It might be remarked, however, that a chemiluminescent reaction occurring in the cell would be expected to have a high radiochemical yield, since the molecule when reacted upon will be adsorbed to some chemical structure in the cell (see below), and will therefore be unable to rid itself of excess energy by collision with other molecules to the same extent as occurs in the homogeneous reaction conducted in the test tube.

Theoretical

The observations set out above indicate that similar processes may occur during the reactions on the chemical carcinogens which take place *in vivo*. If we consider the emission of radiation during reaction to be one of the factors concerned in chemical carcinogenesis, and, indeed, to be the factor which originates the breakdown of the stable economy of a cell or a group of cells, we can evolve a theory which allows some degree of correlation of the great mass of scientific data, chemical and biological, on the subject, and which at least lends itself to further deduction and experimental test.

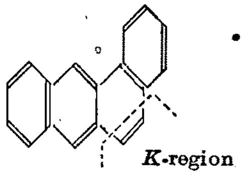
The experiments in chemiluminescence show that here is a phenomenon associated with the oxidation of all the major groups of chemical carcinogens, and the concept that this property initiates the malignant change, at once, finds a common factor for the different series of compounds, and explains, in part, the failure of attempts to correlate chemical structure and carcinogenic action. Furthermore, a theory on this basis provides a link between the chemical carcinogens and the physical carcinogens. That this is a satisfactory link is suggested by the fact that, histologically, tumours induced by chemical and physical carcinogens are remarkably alike, while in some cases they can be distinguished from virus-induced tumours[12,13,14]. The mechanism visualized is as follows: molecules of the chemical carcinogen are supplied continuously over a time period to a localized group of cells by painting the carcinogen on a given area of the skin, or by subcutaneous injection of an oily solution, or by feeding. These molecules pass into the framework of the cells and at some particular point in the cell they come into contact with a hydroxylating system. In the ensuing reaction radiation is emitted and some molecules are hydroxylated. The radiation which is liberated inside the cell is then absorbed by some other molecule of the cell structure, and presuming the radiation to be in the visible or near ultra-violet regions of the spectrum it will cause electronic transitions in this molecule. The result of these transitions will depend on several factors, such as the frequencies of the light absorbed, the strength of the particular chemical bonds affected, and the means which the energized molecule has at its disposal to lose the extra energy; but, at any rate, certain chemical bonds will be momentarily weakened or made more reactive. It may be that, at a certain juncture during the life of the cell, a state of affairs obtains in which the cell structure is under greater strain than normally, and activation of particular chemical bonds by radiation at this time will be effective in producing some structural change; such a juncture is reached during mitosis.

Reference should be made at this point to the interesting article of Haddow[2] on the energetics of the malignant transformation, where he shows that evidence drawn from different sources suggests that the change from normal to malignant cell may be related to some change of energy-level in a certain part of the cell.

In the different studies designed to discover the mode of action of chemical carcinogens an attempt has always been made to relate the carcinogenic potency of the different substances and the extent to which they exhibit the particular property under consideration. The difficulty of making a significant comparison in this way becomes apparent when we come to realize that many factors contribute to the meaning of the apparently straightforward phrase 'carcinogenic potency'. In furtherance of the theory of carcinogenic action proposed above, certain facts which might explain the so-called carcinogenic potency of a substance will be considered.

A point of considerable interest which has emerged from the careful metabolism studies on the hydrocarbons is that the hydroxy-metabolites have the hydroxyl radicals in positions which are not the most chemically reactive ones[15]. The inference from this is that in the reactions which occur *in vivo* the most reactive positions are in some way blocked; and the suggestion has been made that prior to the reaction the molecule is adsorbed to some part of the enzyme system which effects the hydroxylation[16]. This idea is much favoured by the observation that, while the mechanism of enzyme catalysis is not fully understood, one feature which is agreed upon is the formation of an enzyme-substrate complex[17]. This interpretation is given a new significance when it is considered in conjunction with the recent work of the Pullmans[18], who claim that a relationship exists between the carcinogenic activity of a substance and the value of the electron density about a specific bond in the molecule of the substance. The attempt to obtain evidence that such a relationship exists was initiated by Schmidt[19], who also suggested an interpretation[20]. Schmidt's idea is that hydrocarbon molecules possess a region where the electron density is higher than at other parts of the molecule, and that if this density exceeds a certain value the substance is a carcinogen. Carcinogenesis is then supposed due to an interaction between the region of high electron density and some protein molecule whereby a quantal change in the protein molecule is facilitated. The mathematical treatment has been modified and placed on a firmer basis by the Pullmans, while Schmidt's discussion on the significance of the results has been revised by Daudel[21].

The results of the Pullmans' work are capable of an alternative explanation which is supported by chemical facts. A high concentration of electrons about a specific region in a molecule will confer on that region the property of greater reactivity; thus the K-regions to which the Pullmans refer in the hydrocarbons are the most reactive positions in the molecules. When we consider this in the light of the metabolism studies, we see that these K-regions are the positions by which the hydrocarbon molecules will be attached to the enzyme system, thus leaving the positions of secondary reactivity to be hydroxylated. Furthermore, evidence in support of the likelihood of this type of complex formation is offered by the studies of Weiss on the complexes formed between the hydrocarbons and quinones (or polynitro compounds)[22] and on the salts of these hydrocarbons with different acids (perchlorate, sulphate, pyrophosphate)[23]. In both types of structure there is an electron transfer from the hydrocarbon to the other component of the complex and the formation of a linkage of an ionic nature. Such an electron transfer would originate at the K-region of the hydrocarbon molecule. The suggestion is therefore made that the significance of the presence of regions of high electron density in the molecules of polycyclic aromatic hydrocarbons is that it provides them with a means whereby they can attach themselves to a particular enzyme system within a given cell. Since the calculations of the Pullmans have been extended to include other carcinogenic structures, it is possible that a similar explanation might hold in these cases also. If, indeed, a relationship exists between the electron density values at these regions of the molecules and their carcinogenic potency, this would indicate that the ease with which the molecules of a substance can be adsorbed by a particular enzyme system plays a major part in deciding the carcinogenic potency of a compound, and whether it will be a carcinogen at all.



Let us now consider the idea that chemiluminescence is the direct factor causing the malignant change in conjunction with the idea that the ease with which a substance can be adsorbed to a particular enzyme system is the direct factor deciding the relative potency of the substance as a carcinogen. We are then in a position to offer a simple explanation of three interesting facts: (1) that certain chemical substances are carcinogenic, (2) that there are differences in the carcinogenic potency of these substances, (3) that compounds closely related in chemical structure to the carcinogens have no carcinogenic activity. We may suggest that a chemical compound will be carcinogenic if, during its metabolism, sufficient energy in the form of radiation of a particular set of wave-lengths is liberated. The potency of a carcinogen will be dependent on the ease with which it can attach itself to a particular enzyme system; the more easily the molecule is adsorbed, the more readily will the reaction proceed and energy be liberated, thereby presenting a greater probability for structural change in the cell. When the ease of adsorption and consequently the rate of metabolism falls below a certain value, the risk presented to the cell structure is too small and the substance is a non-carcinogen.

The term 'carcinogenic potency' must be interpreted cautiously. Indeed, the relative potency of a carcinogen varies from one cell type to another, and we must qualify the above ideas to cover this point. If the potency of a carcinogen is dependent on the amount of energy liberated during a given time period, it will be directly controlled by the rate of the metabolism of the substance. Other factors which will influence the rate of metabolism of a compound besides ease of adsorption to the enzyme system responsible for the reaction are the ease with which the molecules of the compound can reach that system, and the ease with which the reactants can be desorbed and removed from it to allow for further reaction. These properties will depend on the precise spatial configuration of the molecule of the carcinogen and of the cell structure, and on the intimate interactions between these. It follows that differences in cell structure will affect the rate of metabolism of the carcinogen; it is inferred that they will thus affect the potency of the carcinogen.

OBITUARIES

Prof. P. Lenard

PHILIPP LENARD was born at Pozsony (Pressburg) in Hungary on June 7, 1862. In the town of his birth he was fortunate in finding an excellent teacher of physics, Virgil Klatt, in conjunction with whom he later carried out his first work on phosphorescence. As a young man he studied physics at the Universities of Budapest, Vienna, Berlin and Heidelberg under, among other famous teachers, Bunsen, Helmholtz, Königsberger and Quincke, obtaining a thorough all-round knowledge of theoretical as well as experimental physics. His first senior appointment was, in fact, as professor of theoretical physics in Heidelberg in 1896; two years later he was made professor of experimental physics at Kiel, where he remained until recalled to Heidelberg in 1907 to be Quincke's successor as professor of experimental physics. In 1909 he was made in addition director of the newly founded Radiologisches Institut, which was more or less amalgamated with the physics research laboratory of the University. He remained as professor at Heidelberg until his retirement in 1931. News has recently reached England of his death on May 20, 1947.

Lenard's first paper was on the vibrations of water drops, recalling the fact that Bohr's first paper was the determination of the surface tension of water by jet vibration, and his researches covered a wide field, but he is best known by his pioneering work on cathode rays and electron physics in general. Hertz, whose assistant he was at the time, had shown in 1892 that cathode rays would pass through thin metal foils. Lenard followed this up, and in 1893 succeeded in making a cathode ray tube with a very thin vacuum-tight metal window, with which he obtained outside the generating tube a beam of cathode rays which could either be passed through gases or solids, or be tested in the highest attainable vacuum. His systematic experiments on the passage of cathode rays through matter showed that the absorption was roughly proportional to the density and, further, that it decreased very rapidly with increasing velocity of the rays. He proved that cathode particles of high energy could pass right through atoms, and explained this by his theory that the positive and negative changes within the atom were grouped in tight couplets, which he called 'dynamids'. This theory was, of course, shown to be untenable by Rutherford, but nevertheless Lenard was the first to insist on the charges being grouped so that the space within the atom was relatively empty and penetrable by fast particles. Lenard was the first to prove that the negative electricity released in the photo-electric effect consisted of electrons, although J. J. Thomson's independent demonstration appeared very soon after. For his work on cathode rays he was awarded the Nobel Prize for Physics in 1905.

Lenard was also a pioneer in the field of ionization potential, being the first to show that an electron must possess a certain minimum energy before it can produce ionization. His earliest estimate of 11 volts as the ionization potential of hydrogen, nitrogen and oxygen was a very good one for the rough methods then available. His original experimental disposition was the pattern for many subsequent methods. Another field in which Lenard carried out fundamental work was phosphorescence. First of all in conjunction with Klatt, and later alone and in conjunction with Wilhelm Hausser and others, he studied in great detail the preparation, excitation and emission of light with the alkaline earth and zinc phosphors. In these investigations it was established that the light emission was due to small traces of foreign metal in the sulphide, for example, calcium sulphide, which constituted, with a flux, the bulk of the material, and Lenard put forward the theory that the excitation involved the removal of an electron from the metal atom, which electron was held in certain ways in the surroundings until subsequently released, when its return to the metal atom caused light emission. This is the general basis of the theory now accepted. He also established experimentally that the process was of a quantum nature and, in general, laid the basis for the precise quantitative study of the subject.

He carried out important work in many other directions. He worked out the method of measuring magnetic fields by the bismuth spiral, his work on the electrification caused by splashing was important in its time and he was actively concerned with the electrical properties of flames. Mention must also be made of the important body of work which he carried out, mainly in conjunction with Ramsauer, on the ionization produced by ultra-violet light, which is not known as widely as it might be.

Lenard was personally a difficult man, whose character contained many contradictions. An intimate friend of mine who knew him well once wrote to me: "Was Lenard betrifft, so ist er so klug und so dumm wie immer". He was profoundly disappointed not to have discovered the Röntgen rays, which he had almost under his hand and would have in all probability found within a year or so of the actual date if Röntgen had not anticipated him. He never used Röntgen's name in referring to the rays. He took as a personal affront any inadequate acknowledgment of his work and was incapable of any generosity or even justice towards anyone who, in his opinion, had failed to appreciate any part of his services to science. Although he owed much of his success to Jews, for example, Hertz and Könisberger, and at one time freely acknowledged the debt, he became a bitter anti-Semite and even treated Einstein as not far from an impostor. He refused to fly the Institute flag at half-mast when Rathenau was murdered and was with difficulty saved from popular indignation. He became a whole-hearted supporter of the Nazi regime and of the 'German physics' movement: in fact, he wrote a book called "Deutsche Physik". Yet he had a kindly side to his nature and was often a pathetic rather than a menacing figure. He possibly felt a deep personal need of friendship which he was unable to win or, if he could win it, to retain. His lack of trust in others, his failure to awaken the self-reliance or sympathy of those working under him were the cause that he did not found a great school of physics. It has been suggested, probably correctly, that the clue to his character was that he was a weak personality that sought to protect itself by a hard shell.

As an experimental physicist, Lenard was certainly one of the greatest figures of his time. His work on the physics of the electron was distinguished by a masterly experimental technique and his discoveries had a profound influence on the course of physics, in particular his work on the release of electrons by electron impact and by light. Yet he seemed fated never to achieve supreme greatness. He missed the discovery of Röntgen rays; he came near to the discovery of the true structure of the atom, but just went astray, and his work on light emission was the first to indicate the important part which the release and return of the electron played, but left to Bohr the great advance. He was a whole-hearted enthusiast for experimental physics, whose appreciation of the great men of science of the past times was generous and informed, as can be seen from his book "Grosse Naturforscher" (translated into English under the title "Great Men of Science"). He was a dark genius beclouded by strong personal fears, doubts and envies, but undoubtedly a genius and one who has left an abiding impression in physics.

E. N. DA C. ANDRADE

WE regret to announce the following deaths:

Dr. C. C. Hurst, of Cambridge, known for his pioneer work in genetics, on December 17, aged seventy-seven.

Sir Bernard Spilsbury, honorary pathologist since 1934 to the Home Office, on December 17, aged seventy.

Mr. Benjamin Talbot, Bessemer medallist in 1908 and president in 1928 of the Iron and Steel Institute, on December 16, aged eighty-three.

NEWS and VIEWS

Committee on Industrial Productivity

IN answer to questions in the House of Commons on plans for further development of scientific research to assist industrial production, Mr. H. Morrison, Lord President of the Council, stated on December 18 that he is advised that, while a major contribution to industrial productivity cannot be expected in the short run from current research in the natural sciences, there are considerable possibilities of increased returns, first from the more widespread application of research already carried out in the natural sciences and technology, and, secondly, from current research in the social science field. He had, therefore, decided, in consultation with the Chancellor of the Exchequer, to supplement the work of the Advisory Council on Scientific Policy by setting up a new Committee on Industrial Productivity. The terms of reference of the Committee are: "To advise the Lord President of the Council and the Chancellor of the Exchequer on the form and scale of research effort in the natural and social sciences which will best assist an early increase in industrial productivity, and further to advise on the manner in which the results of such research can best be applied". The main work of the Committee, of which Sir Henry Tizard will be chairman, will be conducted through a number of panels constituted from time to time to investigate and report on various aspects of the problem. In the first instance panels are being set up to deal with technology and operational research under the chairmanship of Sir William Stanier; import substitution, under Prof. S. Zuckerman; the human factors affecting industrial productivity, under the chairmanship of Sir George Schuster; and technical information services, under the chairmanship of Dr. Alexander King. The remaining members of the Committee will include one or more employers (chosen in consultation with the F.B.I. and the B.E.C.); one or more trades union members (chosen in consultation with the T.U.C.); Sir Edward Appleton; Sir Claude Gibb; Mr. Hugh Weeks; Mr. Robert Hall; Mr. E. M. Nicholson; Mr. G. B. Blaker; secretary, Mr. E. D. T. Jourdain.

'Flying Wing' Aircraft

INFORMATION has just been released that an aircraft of the 'flying wing' type has completed its trial flights at Bitteswell Aerodrome, near Rugby. It is known as the *A.W.52*, built by Messrs. Armstrong Whitworth to the designs of Mr. J. Lloyd, their chief designer. The aircraft embodies two fundamental principles, that have developed out of the general progress of aerodynamic research. The abolition of the tail has long been an ideal to some schools of thought. It sets up considerable drag and does not contribute to the performance of the machine, but is necessary for control purposes with the more conventional lay-out of the various aerodynamic surfaces. The Westland-Hill 'Pterodactyl' demonstrated the possibilities of tailless aircraft many years ago. The suppression of as much of the external body as practical requirements of accommodation allow is another obvious trend for the same reason.

Experimental work on high-speed flight has made it evident that swept-back wings are going to be inevitable at transonic and supersonic flight speeds. Again the vital factor appears to be that of control with the less conventional lay-out of the wing surfaces. The *A.W.*52 follows a series of experiments carried out with gliders, and appears to be satisfactory in this respect. Further progress towards even higher speeds should be possible now that greater powers can be envisaged using the internal combustion turbine in conjunction with jet propulsion, and this or similar machines will undoubtedly be used in this way.

Falkland Islands Dependencies Survey

THE Falkland Islands Dependencies Survey has recently acquired a vessel to enable it to carry out its expanding field of work in the Antarctic. The ship, which was named *John Biscoe* by Mrs. Creech Jones, wife of the Secretary of State for the Colonies, on December 16, has a double-skin wooden hull and a displacement of 1,015 tons; she is driven by Diesel-electric power. She carries a crew of twenty-five, and is to take a relief party in the summer to replace about half the party at present occupying the seven observation stations maintained by the Survey in the Antarctic. The new party will carry out geological, meteorological and zoological investigations, and is under the leadership of Dr. V. E. Fuchs, a geologist who has had experience of exploration in East Greenland and in East Africa. The *John Briscoe* has been named in memory of the discoverer of the southern part of Graham Land. The Falkland Islands Dependencies Survey (see *Nature*, March 22, p. 388) was set up under the control of the Colonial Office after the War to take over from the Admiralty the meteorological stations established in the Antarctic in 1943.

Royal Society: Research Appointments

THE Royal Society has appointed Dr. K. Bailey, of the Biochemical Laboratory, Cambridge, to an Alan Johnston, Lawrence and Moseley Research Fellowship for research on the problems of human and animal health and diseases and the biological field related thereto. Dr. Bailey will work at the Biochemical Laboratory in Cambridge on the proteins of muscle fibril. The Royal Society has also appointed Dr. G. S. Dawes, of Worcester College, Oxford, to a Foulerton Research Fellowship in Medicine. Dr. Dawes will work at the Department of Pharmacology, Oxford, on the left ventricle reflex.

Edward Rigby (1747–1821)

EDWARD RIGBY, who was born at Chowbent in Lancashire two hundred years ago on December 27, was a versatile man, distinguished alike in obstetrics, agriculture and civic administration. In medical literature his "Essay on the Uterine Hæmorrhage" (1775) is regarded as a classic, for it clearly differentiated between premature separation of the normal placenta (accidental hæmorrhage) and placenta prævia (unavoidable hæmorrhage). It was translated into French and German, and up to the hour of his last illness the author was employed in the preparation of a sixth edition. A scientific agriculturist, Rigby experimented on his own farm at Framingham Earl, near Norwich, and the reputation of his writings on that subject led to his election as honorary member of the Philadelphia Society. In 1805 he became mayor of Norwich, and he is said to have "supported the chair with dignity and hospitality". He established in 1786 the Norfolk Benevolent Medical Society for the relief of the widows and orphans of medical men, introduced the flying shuttle to the manufacturers in Norwich, and in 1812 started vaccination in the city. Simple, placid and benevollent, Rigby was a delightful companion and a good conversationalist. He died on October 27, 1821, in his seventy-fourth year. His "Letters from France" constitute an animated and fascinating record of the stirring days at the outbreak of the French Revolution, besides forming a useful survey of the country's agriculture at the time. Rigby's son Edward (1804–60) was a well-known London obstetrician.

New Nuclear Reactions

"NUCLEAR Transformations in the new High Energy Ranges" is the title of an address delivered by Prof. Glenn T. Seaborg, of the University of California, at a meeting of the American Chemical Society in New York on September 15 (see *Chemical and Engineering News*, 25, 2819; 1947). The great progress made recently in constructing new powerful machines for the acceleration of charged particles affords the possibility of bombarding targets with electrons of 100 MeV., and with deuterons and helium ions of 200 and 400 MeV. respectively. Entirely new nuclear reactions have been observed; for example, $^{75}_{33}$As, bombarded with 400 MeV. helium ions, produces among other atomic species the well-known $^{38}_{17}$Cl. This means that the arsenic atom has lost no less than 16 protons and 21 neutrons, not counting the two protons and two neutrons shot into it at the start of the reaction. To distinguish such transmutations from the ordinary nuclear reactions in which only one or two particles are ejected, and from fission reactions in which the nucleus is broken into two fragments, the term 'splintering reaction' is proposed. Further, under such strong bombardment fission can be enforced in such elements as bismuth, lead and thallium, and even in an element so low in the periodic table as tantalum; but as the secondary particles emitted have a much smaller energy, there is no possibility of inducing a chain reaction such as in uranium. Many radioactive isotopes so far unknown have been found as a result of these new nuclear reactions, which have still further widened the field radiochemists are called upon to explore; the splintering often leads to neutron-deficient isotopes and increases therefore in a welcome manner the comparatively small number of positron emitters among the artificial radio-elements. Some of them may find application as tracers. Still more important may be the physical aspects of this extension of the energy range; the creation from energy of mesotrons and, if the region of billions of electron-volts can be reached, also of neutrons and protons, seems now a possibility.

Special Libraries in Australia

RAPID growth in the appreciation of the value of accurate and up-to-date information in science and technology was marked during the last decade. This resulted in recognition that the work of librarians in special libraries and of information officers has a character of its own, and in the consequent formation of associations providing a platform for the discussion of common interests. The Association of Special Libraries and Information Services (A.S.L.I.S.) in Melbourne, Australia, is one of these, and it is to be congratulated on the launching of its journal, *Information*, in June 1947. This first issue contains, besides introductory matter, the first part of an article on documentary reproduction, another on patents in information, glimpses of the B. J. Ball, Ltd., library in Melbourne, and the constitution of the Association. An exchange corner for periodicals, abstracts of relevant literature, and questions and answers on the universal decimal classification are other features which will appeal to members. Although printing difficulties may make the appearance of the journal infrequent at first, it has made a good start. It should, perhaps, be mentioned that the Australian organisation A.S.L.I.S. is quite independent of the Association of Special Libraries and Information Bureaux (A.S.L.I.B.) in Great Britain, though the two are in very cordial relationship.

Indians of the South-Eastern United States

THE historical Indian tribes of the south-eastern United States are diverse in language, but they share so many important characteristics that they form a cultural province. This is illustrated by the arrangement of Mr. Swanton's massive work (Smithsonian Institution: Bur. of Amer. Ethnology, Bull. 137. Pp. xiii+943+107 pl. Washington, D.C.: Gov. Print. Office. 2.75 dollars), in which a brief, purely historical sketch of each individual tribe is given first, leaving the material culture to be dealt with as a whole. The book may be considered as supplementing and bringing up to date the relevant parts of the great two-volume Handbook of American Indians North of Mexico, edited by F. W. Hodge, published as Bulletin 30 of the same series in 1907 and 1910. The author regards it principally as a collection of source materials, and as such he hopes that it will be useful to future students. This hope should be fully realized, and in addition it will be a most useful book of reference. Some of the plates are not well chosen. It is difficult, for example, to see what is to be learnt from the rather distant group, in Edwardian dress, in front of a modern wooden building, labelled "Ladies Relief Society of the Church of Jesus Christ of Latter Day Saints, Catawba Reservation" (Plate 5). The space occupied by this and some others might have been better employed in illustrating objects of material culture.

Bibliography of Seismology

VOLUME 13, No. 19 of the *Bibliography of Seismology*, published by Dr. Ernest A. Hodgson from the Dominion Observatory, Ottawa, Canada, covers items 6,047–6,142 and carries the bibliography to the end of June 1946. This valuable publication, which deals with pure and applied seismology and subjects throwing light on them, covers in this issue world books, papers and works published on the Continent of Europe during the years 1939–45, together with a small list of patents. There are fourteen items from Holland including an obituary notice of Dr. G. Van Dijk (1877–1940), L. P. G. Koning on deep focus earthquakes (items 6,094–95), F. H. van Rummelen and S. W. Visser on Dutch earthquakes, and a text-book on seismology by S. W. Visser (items 6,135, 6,137–38). The items from Finland, five in number, consist of four papers on isostasy and one on pure seismology, namely, Eijo Vesanen's "Ueber die typenanalytische Auswertung der Seismogramme" (*Ann. Acad. Sci. Fennicæ*, A, 3, Geologica-Geographica, 5, pp. 244. Helsinki, 1942). Three items from France include obituary notices of Dr. Edmund Rothé and Dan Barfod La Cour and an article on French geophysics during the War. Item 6,107 contains references to a most important topical seismological question, namely, the use of the seismograph as a meteorological instrument; by means of microseisms tropical storm and cyclone centres at sea can be located and tracked. There is a list of the seismological items published in *Nature*.

An Unusual Asteroid

AN asteroid discovered in August by C. A. Wirtanen, Lick Observatory, is described in *Sky and Telescope* of October. Its magnitude at the time of discovery was 15, and it is estimated that its diameter is only a few miles. Its orbit is nearly circular and lies close to that of Mars, approaching the orbit of Mars to within 6 million miles; but its least distance from the earth is about 50 million miles. Its period is nearly 2·3 years—the shortest period of any asteroid with the exception of Eros.

Institution of Mining and Metallurgy: Officers for 1948–49

THE following have been elected officers of the Institution of Mining and Metallurgy for the session 1948–49: *President*, Mr. Sydney E. Taylor; *Hon. Treasurer*, Mr. Robert Annan; *Vice-Presidents*, Mr. G. Keith Allen, Mr. Donald Gill, Mr. V. Harbord, Colonel L. C. Hill, Sir Arthur Smout and Brig. R. S. G. Stokes. Mr. S. E. Taylor, the new president, was educated at Cambridge, where he read engineering science. He joined the technical staff of Messrs. John Taylor and Sons, managers and consulting engineers to mines in many countries, in October 1922, and became senior partner in 1941. In 1924 he visited Brazil, and since 1923 has paid numerous visits to India in connexion with the management of the mines on the Kolar Gold Field in Mysore State, and the re-opening of the Hutti gold mine in Hyderabad State.

Announcements

THE Royal Society is compiling a list of British scientific societies, together with the names of their officers, etc. As it is desired to make this as comprehensive as possible, it would be appreciated if any secretaries of such societies, who have not yet received a questionnaire from the Royal Society, would inform the Assistant Secretary, Royal Society, Burlington House, London, W.1.

TRINITY COLLEGE, Cambridge, offers research studentships and Dominion and Colonial exhibitions every year, and elections will take place in July 1948. Research studentships are open to graduates of universities other than Cambridge who are not more than twenty-six years of age. The exhibitions are open to undergraduates as well as those wishing to undertake research. Applications, to be sent through the head of the candidate's university, must reach the Senior Tutor, Trinity College, Cambridge, not later than May 1, 1948.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications

Molecular Weight of α-Amylase

PROF. KURT H. MEYER and his co-workers[1,2] have recently succeeded in the crystallization of α-amylase from pig's pancreas. The molecular weight of the substance, kindly supplied by Prof. Meyer, has been determined from sedimentation and diffusion experiments. The dried substance was dissolved in a buffer solution of pH 8·4, with a molarity of 0·2 in sodium chloride, 0·02 in boric acid and 0·005 in borate.

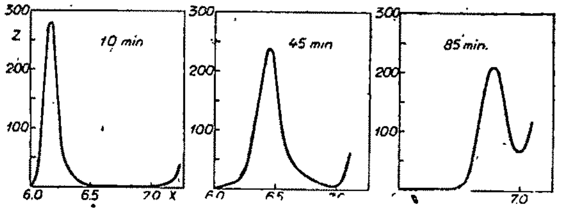

Fig. 1. SEDIMENTATION CURVES FOR α-AMYLASE

Ultracentrifuge measurement. The sedimentation diagrams of Fig. 1 were obtained by centrifuging at 65,000 r.p.m. The diagrams show one definite peak, characteristic of a uniform substance[3]. The concentrations of amylase used are shown in the table.

Conc. of amylase %	s_{20} (in S units)
0·09	4·63
0·18	4·32
0·22	4·44
0·26	4·50
0·30	4·38
0·66	4·64

The value of the sedimentation constant is evidently independent of the concentration of amylase. The average value is 4·50 S.

Diffusion measurement. The determination of the diffusion constant was carried out according to Lamm's scale method[4,5] in a diffusion cell of steel[6]. The resulting curves are shown in Fig. 2.

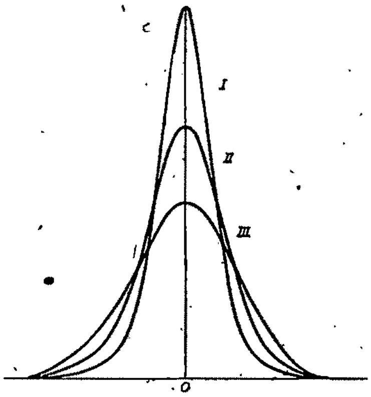

Fig. 2. DIFFUSION CURVES
I, after 20,100 sec.; II, after 42,700 sec., and III, after 80,900 sec.

The diffusion constant was calculated by two independent methods. Values of $D_A = 7 \cdot 89 \times 10^{-7}$ and $D_m = 8 \cdot 19 \times 10^{-7}$ were obtained. Hence, the agreement between the two methods of calculation is good. The average value of $D = 8 \cdot 05 \times 10^{-7}$ is used in the following.

The molecular weight was calculated according to Svedberg's formula: $M = \dfrac{R T s_{20}}{D(1 - V\rho)}$, where R is gas constant, T is absolute temperature, s_{20} is sedimentation constant, D is diffusion constant, V is partial specific volume of the solute, ρ is density of the solvent.

The value of V was 0·70 ± 0·02, kindly determined by Prof. C. Drucker. Using these values, the molecular weight of this α-amylase is 45,000.

Structure of Starch: Mode of Attachment of the Side-chains in Amylopectin

ESTIMATIONS of the proportion of glucose residues present as end-groups in the amylopectin component of starch have shown that some 5 per cent of the glucose residues occur as terminal groups. Since amylopectin has a high molecular weight, of the order of 10^6, a branched-chain structure must be present in the molecule. The main features of the structure are indicated diagrammatically in Fig. 1[1], where (*A*), (*B*), (*C*), etc., are chains containing on the average 20–24 1:4-linked α-gluco-pyranose residues, each chain being united through C_1 of its first glucose residue to one of the glucose residues in another chain. The location in the chain of this glucose residue is not known, but it is clear that it must have three of its hydroxyl groups, namely, those at C_1, C_4 and at the carbon atom involved in the junction, occupied by linkages to other glucose residues. Two hydroxy groups remain free, and it follows that an investigation of the dimethyl glucose obtained on hydrolysis of a completely methylated amylopectin should enable the mode of linkage to be ascertained. Experiments on these lines showed that 2:3 dimethyl glucose was present in the hydrolysis products[2], and it was inferred that some at least of the side-chain linkages were through C_6 of the glucose residues concerned. Uncertainty is caused, however, by the experimental difficulty encountered in the complete methylation of amylopectin and by the fact that trimethyl glucose tends to undergo some demethylation in contact with methanolic hydrogen chloride. An effort to minimize these difficulties was made by using for the methanolysis a fully methylated but highly disaggregated sample of starch of low mole-

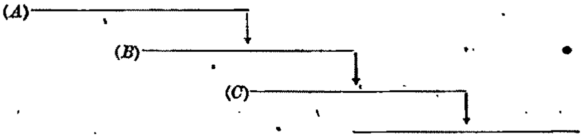

Fig. 1

cular weight[3]. Again, however, 2:3-dimethyl glucose predominated in the dimethyl hexose fraction.

An alternative method of approach was clearly desirable, and this we have endeavoured to provide by a development of the periodic acid method of oxidation of glycols[4]. Inspection of Fig. 2 will show that when the side-chain is attached to C_6 there remain in the glucose residue two contiguous OH groups at C_2 and C_3. Oxidation with periodic acid will therefore disrupt the bond between C_2 and C_3, and after subsequent hydrolysis the sugar residue involved in the branching will no longer be recoverable as glucose. On the other hand, if the side-chain junction is at C_2 or C_3, no α-glycol groupings remain and there will be no attack by periodic acid. In these circumstances the glucose residue remains intact and will be recoverable as glucose after hydrolysis. It follows that oxidation by periodic acid followed by hydrolysis and examination of the products should give information about the mode of linking, provided methods are available for the detection and estimation of small quantities of glucose in admixture with aldehydic and acidic products. These were found in the paper chromatogram method of Partridge[5] and in the recently described quantitative development of this technique[6].

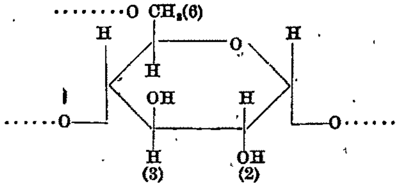

Fig. 2

This procedure has now been applied to starches of various origins, namely, potato, acorn, sago and waxy maize, and also to the limit dextrin obtained from waxy maize starch by the action of purified β-amylase. In every case glucose was just detectable, but in such small amount (less than 1 per cent by weight of the starch used) that its quantitative significance is uncertain. On the other hand, the point of special interest which emerges is that it now becomes clear that, in all these amylopectins, by far the greater proportion of the side-chain linkages (more than 75 per cent) are of the 1 : 6 variety, and at most only a small proportion of them can involve either C_2 or C_3, a result which is of particular interest in connexion with theories of the enzymic synthesis of amylose and amylopectin from glucose 1-phosphate. The method is obviously applicable to other problems in polysaccharide chemistry, and it has recently been utilized by Mr. A. E. Flood in this laboratory in a demonstration of the branched-chain structure of several plant gums, including xylan.

Structure of Amylopectin

Since starch can be split into maltose, the opinion has been widespread that starch is composed of chains of the maltose type[1]. Some authors, however, suggested a branched or netted structure[2,3]; comparative measurements of molecular weight and viscosity were definitely in favour of a branched structure. Haworth[4], on the other hand, deduced from end-group assays that the molecular weight is low and therefore starch is composed of straight chains of not more than twenty to thirty glucose units. However, such a view could not be maintained. Some years ago it became quite evident[5] that most starches are made up of two polysaccharides: one unbranched, for which we proposed the old name of 'amylose', and one branched, 'amylopectin'.

While the constitution of amylose seems to be well established, the problem of amylopectin constitution is still open. Haworth[6] has proposed a structure in accordance with Fig. 1 which he calls 'laminated', whereas Meyer and Bernfeld[7] favour a structure with irregular branches like the branches of a bush (Fig. 2).

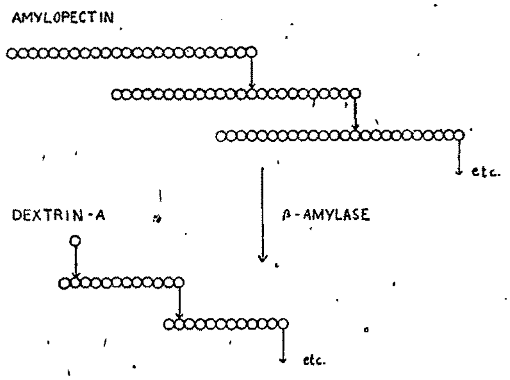

Fig. 1. Structure of amylopectin and limit dextrin according to Haworth

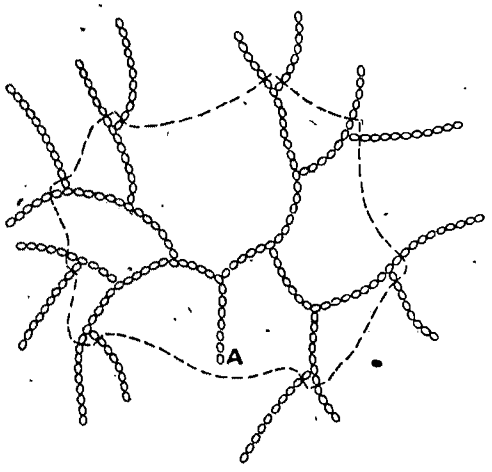

Fig. 2. Structure of amylopectin, according to Meyer. *A* is reducing end-group; limit dextrin inside the dotted line

It is possible to decide between these two formulæ when examining the properties of the limit dextrin *A* obtained by action of β-amylase on amylopectin. If the 'laminated' form were present, a very long-shaped molecule would arise, whereas the 'branched' amylopectin would yield a more compact form (indicated by the dotted line in Fig. 2). If the acetylated dextrin were composed of fibrillar molecules, its solution would easily be torn into threads, and its films obtained by evaporation would exhibit a considerable solidity such as has been found for amylose acetate and the irregularly constituted lichenin acetate[8]. If it is branched, on the other hand, it would behave like acetylglycogen or analogous products, that is, the films would be extremely brittle. In fact, we found this to be the case: the acetyl-dextrin evaporated on a glass-plate could not even be detached as film. This behaviour is definitely against the Haworth formula and is in favour of our own assumption.

[8] Meyer, K. H., and Gürtler, P., *Helv. Chim. Acta*, 30, 751 (1947).

Prof. Meyer's brief sketch of the history of the development of starch structures neglects some essential facts. Before starch could be formulated as consisting of repeating maltose units, proof had to be provided that maltose was preformed in starch and was not a product of synthesis by the enzymes present during starch degradation[1]. Moreover, the constitutional formula of maltose had to be determined before any such formulation of starch could be attempted[2]. The end-group method of assay showed that if starch were represented as a very large molecule, it possessed many end-groups. As early as 1936 [3], in an article on the size of polysaccharide molecules, I made these statements: "it has never been claimed by the present author that the chemical end-group method of determination of chain length corresponds with the particle size", and also "a measurement of particle size must take account of the physical molecule and the molecular aggregate. This may involve not only aggregation to increase the length of chain but also the lateral combination of the chains."

In 1934 [4], I advanced the hypothesis that large molecules containing many end-groups could be formulated by the cross-linking or mutual combination of polymeric units of limited chain-length, and I illustrated this concept in a formula for xylan. In 1937 [5], I advanced the same hypothesis in the laminated formulæ for both starch and glycogen. The nature of this polymeric bond uniting chains of limited length was postulated as an ordinary covalency link although alternatives were not excluded. The nature of this link between adjacent chains was determined later[6]. It has been the procedure of this School to advance formulations only with accompanying experimental evidence. It has been preferred to proceed stage by stage in accordance with the growth of evidence, rather than to present highly speculative formulations with little experimental background.

Evidence that amylose should be represented as continuous chains of ninety or more glucose units, largely unbranched, was published in 1942 [7] after examination of a specimen of the synthetic amylose of C. S. Hanes. This extended and confirmed the view of K. H. Meyer, who had separated amylose by Baldwin's method[8] and had shown that it was completely broken down to maltose by β-amylase, and that it did not give dextrin-*A* as a by-product as does amylopectin[9]. The laminated formula for amylopectin was advanced as a first approximation only, and is not to be regarded as the final or complete structure of amylopectin. It still serves to explain most of the known experimental facts. The multibranched structure advanced by K. H. Meyer is a development of the same concept; but at the present stage of our knowledge it seems to be premature and needlessly complex.

The point made by him above that acetylated dextrin-*A* should, on the basis of our formulation, yield films resembling amylose acetate rests on very slender evidence; and much more adequate experimental investigation will be necessary to support his contention.

*neo*Pentyl Alcohol and Steric Hindrance

In a note under this title, Gerrard and Nechvatal[1] have reported the conversion of *neo*pentyl alcohol, $(CH_3)_3C.CH_2.OH$ (here written ROH), by thionyl and phosphorus halides into the esters RO.SOCl and RO.PCl_2, *inter alia*. They remark that Whitmore and Rothrock[2] demonstrated the resistance of *neo*pentyl alcohol to the replacement of its hydroxyl group by halogen, through the agency of thionyl chloride and phosphorus tribromide. They add that we[3] have attributed this to the steric hindrance of what they call "end-on approach" to the α-carbon atom. They state that Whitmore and Rothrock leave the impression that *neo*pentyl alcohol does not react at all with the halides specified; but that the work of Gerrard enabled Gerrard and Nechvatal to predict the probability of an easy "broadside approach" of the reagents. We should like to add some points to this statement of the relation between the different investigations.

Whitmore and Rothrock first showed that *neo*pentyl alcohol exhibits considerable resistance to the substitution of its hydroxyl group *as a whole*, for example, by halogens; though they reported some displacement of the hydroxyl group by means of hydrogen bromide and phosphorus tribromide. They also, however, observed a fairly facile substitution *of the hydrogen atom* of the hydroxyl group in the formation of an acid ester with sulphuric acid[2]. The difference of behaviour in the two types of replacements has been fully confirmed. We developed more quantitatively the subject of replacements at the α-carbon atom and interpreted the relative difficulty of such reactions in terms of steric hindrance[3]. For example, adopting the conclusion of Cowdray, Hughes, Ingold, Masterman and Scott[4], that the first stage in the formation of halides from alcohols by reagents such as hydrogen bromide, thionyl chloride and phosphorus trichloride is the production of intermediates such as ROH$_2$Br, ROSOCl or ROPCl$_2$, we adduced evidence[3] that all the routes by which such complexes could normally yield alkyl halides are very much restricted in the *neo*pentyl system. Consequently, such intermediates should be easier to isolate in this system than in others. It is therefore very satisfactory that, while Whitmore and Rothrock had already isolated ROH$_2$Br in this system, Gerrard and Nechvatal have now isolated the esters RO.SOCl and RO.PCl$_2$.

The points we wish to make are, therefore: (1) that the reactions which Gerrard and Nechvatal have realized belong to the class (substitution of hydroxylic hydrogen) of those which Whitmore and Rothrock, among others, found to be easy, not the class (substitution of hydroxyl) which they showed to be difficult; (2) that our interpretation[3] of Whitmore's work involved the conclusion which Gerrard and Nechvatal's results support; and (3) that we did not conclude from Whitmore and Rothrock's paper that *neo*pentyl alcohol does not react at all with the reagents specified above. Gerrard and Nechvatal quote as follows from Whitmore and Rothrock's paper: "The inactivity of *neo*pentyl alcohol to heat and reagents has been demonstrated". However, this sentence is taken from the very brief final summary, and was clearly intended as a general and relative statement, not as contradicting part of the text of the paper.

Structure of Cyclopropane

DR. WALSH has defended his suggested structure[1] for the compounds ethylene oxide and cyclopropane in terms of a molecular orbitals picture based on the assumption that the carbon atoms are in the trigonal, or near-trigonal, state. The calculations by Linnett[2] of the CH-bond force-constants are consistent with trigonal bonding.

One would expect to find that the H—C—H angles in cyclopropane and ethylene oxide should lie close to 120° if the carbon atoms are indeed trigonally bonded. It is relevant, therefore, to direct attention to the results of a recent electron-diffraction study on cyclopropane, reported by Bastiansen and Hassel[3]. The photographs were obtained using a rotating-sector camera, and the results are probably more accurate than those obtained by Pauling and Brockway[4] some years ago. Bastiansen and Hassel find the following values for the distance and angle parameters:

$$\text{C—H} = 1{\cdot}08\text{ A.}; \qquad \text{C—C} = 1{\cdot}54\text{ A.};$$
$$\angle\,\text{H—C—H} = 118{\cdot}2^\circ; \quad \angle\,\text{H—C—C} = 116{\cdot}4^\circ.$$

The uncertainty in the angles is quoted at ± 2°.

Spectroscopic studies by Smith[5] have provided the value for one of the moments of inertia in cyclopropane ($I_B = 41{\cdot}91 \times 10^{-40}$ gm./cm.^{2}). The calculated moments of inertia of the Bastiansen–Hassel model are $I_A = 68{\cdot}14 \times 10^{-40}$, $I_B = I_C = 42{\cdot}68 \times 10^{-40}$. If the C—C distance in the proposed model is reduced from 1·54 A. to 1·52 A., this alteration in itself is sufficient to give complete agreement with the experimental I_B. Bastiansen and Hassel do not quote the limits of error in the C—C distance determination, which, however, can scarcely be less than ± 0·02 A. Some justification for assuming that C—C may be slightly less than 1·54 A. follows from Pauling and Brockway's estimation of C—C = 1·53 ± 0·03 A., and from O'Gorman and Schomaker's[6] estimation of C—C = 1·52 ± 0·02 A. in monochlorocyclopropane.

Although the structural data are not yet complete, the 'most probable' cyclopropane structure would seem to agree with the assumption of near-trigonal bonding, at least in respect of the CH bond-length, force-constant and HCH angle. On the other hand, the C—C distance (~ 1·54 A.) corresponds with that of C—C found in the paraffin hydrocarbons, suggesting relatively little double-bond character in the C—C bonds. From the point of view of bond-length, it is satisfactory to represent the carbon–carbon bonding in cyclopropane by single C—C bonds: this representation, however, is not satisfactory in respect of the C—C bond-energy. The thermal data on cyclopropane indicate a marked *weakening* of the C—C bonds relative to C—C in diamond or ethane[7]. In regard to this latter point, it is perhaps significant that the assumption of trigonal bonding in cyclopropane nevertheless leaves a system in which the formation of σ or π C—C bonds occurs under conditions of angular strain.

I AM grateful to the Editors for affording me the opportunity of writing a final letter in this discussion. The fundamental idea underlying my earlier letter[1] was that the carbon atoms in cyclopropane and ethylene oxide were in a hybridization state close to that of the carbon atoms in ethylene. The evidence was then strong. Dr. J. W. Linnett has since pointed out that the CH stretching force-constant in these molecules is much closer to the ethylene than to the paraffinic CH$_2$ value. This developed a point already made, that the height of the strong Raman frequencies indicated the same conclusion. The Bastiansen–Hassel determination of the angle HCH in C$_3$H$_6$ as 118° ± 2 provides further strong evidence for my fundamental point. (The smaller angle in the 1,1 dichloro derivative (112° ± 4 [2]) is expected since the angle ClCCl in the comparable 1,1 dichloro ethylene is reported as several degrees smaller than the angle HCH in ethylene.) Dr. H. A. Skinner's finding of accord between the Bastiansen–Hassel model and the measured moments of inertia reinforces the argument. Evidence from widely separated sources all fits together and shows that ethylene oxide and cyclopropane can be regarded as formed from CH_2 groups the carbon atoms of which are in a state of hybridization close to that of ethylenic carbon atoms. It is this most significant conclusion that a successful theory of these molecules has to explain and the implications of which have to be drawn out.

My suggested representation of the molecules was a natural one to make in order to convey an inkling of the remarkable properties enumerated above and in the second paragraph of my earlier letter[1]. Sir Robert Robinson[3] takes the usual formula to represent only the position in space of the atoms involved. This appears difficult. If we represent a bond C—C, we naturally tend to associate with it properties similar to those of the C—C bond in ethane. If we represent it C=C, we associate it and its neighbours with properties of ethenoid groups and their neighbours. Mr. L. Bateman[4] quotes Ingold as saying symbols are simply intellectual scaffolding. This seems the wiser view. My formulæ form such scaffolding. They help in suggesting the properties of linkages from the ring to other atoms or groups. It is not true that, by making the mental reservation that three resonance structures exist for cyclopropane, 'each unique feature' of the formula 'is destroyed'[3]. The olefinic properties of the CH-bonds, for example, remain. It has to be emphasized, however, that the analogy between cyclopropane and ethylene is primarily one of *valencies*. The *bonds* are only similar if similar valencies are joined to similar atoms. The CH-bonds are similar, but the two C-valencies used to bind *one* other carbon atom in ethylene are used to bind *two* other carbon atoms in cyclopropane. It is not to be expected that the CCC ring of cyclopropane should show, for example, olefinic frequencies. Controversy over the formulæ has tended to arise according as emphasis has been laid on properties of the ring binding or of the bonds external to the ring.

Knowing the approximate valencies used, it follows that the picture of overlapping atomic orbitals in cyclopropane is as (VII) of my earlier letter[1]. On symmetry grounds one then expects the density pattern for the electrons to be as (VIII) of that letter. It is here that Mr. T. M. Sugden's letter[5] is valuable, for it provides a justification of this in molecular orbital theory. His treatment may be simplified by considering only interaction in the ring plane of $2p$ and (separately) sp^2 valencies. Each of these gives rise to three molecular orbitals, one single and two degenerate. But whereas for the sp^2 valencies the single orbital is bonding and the degenerate ones anti-bonding, for the $2p$ valencies the reverse holds. Sugden's diagrams show how this arises. There are thus just three bonding orbitals into which we can fit without difficulty the six CC electrons, so that some light is shed on the stability of cyclopropane. It is easily seen that the occupied molecular orbitals give a density pattern as (VIII) of my earlier letter, two electrons being in *a* and four being found in *b* or *d* or *e*.

As already stated[1], and as Sugden's Fig. 3 also shows, this pattern can be regarded as the C_2H_4 pattern generalized to an extra dimension. In molecules of this type each carbon atom must have a hybrid atomic orbital pointing towards the molecular centre of gravity and a $2p$ atomic orbital of axis at 90° to this. These essential features are retained if we replace one of the CH_2's by digonal C. The hybrid orbital pointing towards the ring centre is now sp, the two hydrogen atoms are replaced by a second $2p$ orbital of axis at 90° to the ring plane, and a second sp hybrid projects at 180° to the first. One could build a second ring with a plane at 90° to the first. The existence of spiro-pentane with two rings at 90° is thus natural. It is to C_3H_8 as allene is to C_2H_4. Further homologues (in which adjacent rings are always at 90°) are possible by changing other CH_2 groups for digonal C atoms. A special case is the group usually pictured , of stability natural on the present, but not on older, views. These matters are described in detail in my forthcoming paper.

Interaction of Thionyl Chloride and Hydroxy Compounds

Human and Mills[1] have generalized the procedure of Carré and Libermann[2], who prepared, by adding an equimolecular amount of pyridine, the chlorides of the few acids which until then had withstood the action of thionyl chloride. Gerrard and French[3] found it unnecessary to use an equimolecular amount of pyridine in the interaction of thionyl chloride and hydroxy compounds, and proposed to modify the Darzens' procedure[4] by adding the thionyl chloride to a hydroxy compound with a few drops of a tertiary base, and heating for four hours at 65–80° C., which gives them the corresponding chloride.

I pointed out in 1944[5] the catalytic character of the action of pyridine or its hydrochloride: a few drops of it are enough to lower the decomposition point of chlorosulphites some 50–100° C. However, the way the procedure of Gerrard and French is proposed does not demonstrate its universality: these authors chose as examples those alcohols which react with thionyl chloride in a normal way, and do yield alkyl chlorides even without pyridine. It was interesting to see whether that process will permit the preparation of alkyl chlorides with those alcohols which lead to unusual reactions with thionyl chloride. The main interest of Darzens' procedure is its universal application.

The interaction of cyclohexanol and thionyl chloride had given rise to a controversy settled only by Kyrides[6]. Hence we treated cyclohexanol according to Gerrard and French's procedure and only obtained cyclohexene, cyclohexanol and some residual cyclohexyl sulphite. The results were due to the action of hydrogen chloride on cyclohexyl sulphite, in analogy with what we observed[7] in the action of thionyl chloride on phenols; which has been tested by saturating cyclohexyl sulphite with hydrogen chloride. After four hours contact, hydrogen chloride was removed under vacuum and the residue distilled under atmospheric pressure. The whole product had passed over before 160° C., and in that distillate we found only cyclohexene and cyclohexanol.

To see whether that decomposition was not due to pyrolysis, we submitted pure cyclohexyl sulphite to distillation under atmospheric pressure. Decomposition took place, with an abundant evolution of sulphur dioxide; rectification of the distillate showed pure dicyclohexyl oxide, b.p. 270°/760 mm. and 131°/12 mm.

Hence the following modification of Darzens' procedure: 1 mole of thionyl chloride is introduced into 2 moles of hydroxy compound, with circulation of a stream of dry air, until hydrogen chloride ceases to be evolved; 1·2 more moles of thionyl chloride is then added and left for 24 hours. Only then some drops of pyridine are added, and the mixture is heated for four hours on a water-bath to remove the sulphur dioxide. Pyridine only lowers the decomposition point of the corresponding chlorosulphite. Distillation then gives an excellent yield of cyclohexyl chloride (b.p., 141° C.; n_D, 1·462; D^{18}_{4}, 0·9765).

The same procedure gave us, with yields of nearly 95 per cent, ethyl α-chloropropionate, ethyl phenylchloroacetate, ethyl diphenylchloroacetate.

Response of New-born Children to Hypertonic Solutions of Sodium Chloride and of Urea

From all that is known about the renal function of new-born infants, it is now clear that their glomerular filtration-rates are considerably lower than those of adults, and also their clearances of urea and sodium chloride[1]. These discoveries have an important bearing on clinical practice, but much more information is required about the way in which the kidney of an infant reacts to changes in the internal environment. Accordingly, some experiments have been made to study the response of the kidney in new-born infants to a considerable rise in the osmotic pressure of the body. The children used for these experiments had all been born with inoperable meningo-myelocœles. Healthy adults have been used as controls.

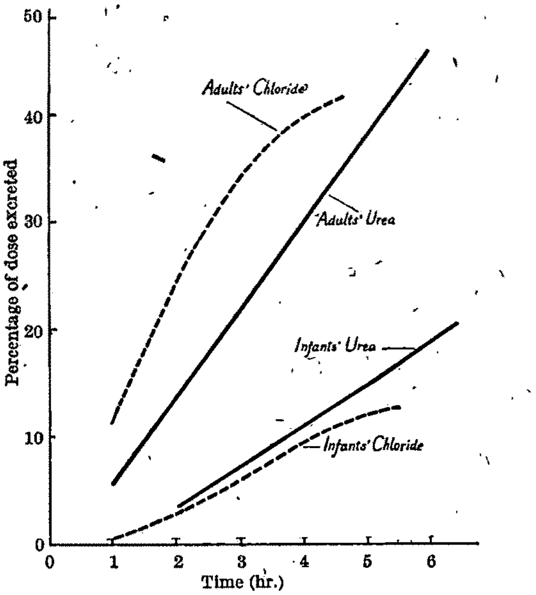
All the subjects were deprived of water for about 12 hours before the tests began. Sufficient sodium chloride was then given intravenously as a 10 per cent solution to raise the serum concentration of chlorine to about 135 m.eq./l. in the adults and to about 147 m.eq./l. in the infants. The results may be summarized as follows:

(1) A diuresis was produced in both infants and adults.

(2) On a basis of surface area, this diuresis was much smaller in infants than in adults. The greatest rate of flow in an infant has so far been 2·7 c.c./1·73 sq. m./min. All adults have exceeded a rate of 7·6 c.c./1·73 sq. m./min., and one has reached a value of 19·1 c.c./1·73 sq. m./min.

(3) The administration of sodium chloride tended to raise rather than lower the osmotic pressure of the urine in infancy, but it greatly reduced the osmotic pressure of the urine in adults[3].

(4) The infants excreted the administered sodium chloride much more slowly than adults (see graph). In one hour they excreted less than 1 per cent of the dose given, and in four hours 9·5 per cent. In the same times adults excreted 11 and 40 per cent of the dose. When comparisons were made on the basis of surface area, it was found that the maximum rate of excretion of chloride by adults was eight times that of infants. A feature of the experiments in both adults and infants has been that the diuresis produced by the salt solutions fell off while the concentration in the plasma was still high. No satisfactory explanation of this can be suggested at present.



Urea has been given by mouth as a concentrated solution to adults and infants in quantities sufficient to raise the blood urea to about 30 m.mol./l. The response at both ages has had the same general characters as the response to sodium chloride (see graph), but the differences between the adults and the infants have not been so great and the maximum output of urea by the adults per unit of surface area has not been more than six times as great as that of the infants. The diuresis, moreover, which at its peak was only about one third as great as that produced by the salt solutions, declined more slowly and the rate of excretion of the urea was better maintained.

It is evident that the kidneys of human infants respond better than those of new-born rats to the administration of strong solutions of sodium chloride and urea[3], but that the responses are essentially similar in nature. It is likely that these signs of immaturity will be demonstrable in all young mammals, but that no two species will show them to the same degree.

Hypertension after Bilateral Nephrectomy in the Rat

Jeffers, Lindauer, Twaddle and Wolferth[1] reported in 1940 that removal of three of the four kidneys in a pair of parabiotic rats resulted in hypertension in the nephrectomized animal. Grollman and Rule[2] found in two pairs of parabiotic rats that removal of the kidneys in one animal sufficed to induce hypertension. When these experiments were repeated by one of us (E. B.-M.) a definite rise in blood pressure was found only in three out of twenty-three pairs, however.

We have modified the procedure by joining three rats in parabiosis, one bilaterally nephrectomized between two normals. In such case the survival-time of the nephrectomized rat is regularly prolonged and it remains in a good general state for a week or longer. In all the six trios prepared, definite hypertension was observed in the nephrectomized animal. A moderate rise in blood pressure was also observed a few times in one or both of the normals. The rise in pressure in the nephrectomized animal occurred two to four days after the removal of the kidneys and the highest figures noted were 156, 144, 170, 190, 172 and 144 mm. mercury.

These results led us to investigate more systematically the blood pressure of single rats after total nephrectomy. A total of 39 normal adult rats were nephrectomized and the blood pressure determined daily until death occurred. A definite rise was observed in 13 rats (33 per cent) (see table); in all these, blood urea was high. In 14 animals a solution of Ringer with 0·5 per cent gelatin was allowed to flow through the peritoneal cavity at a rate of 1 ml. an hour during 1–3 hours, the animal being anæsthetized with nembutal (30 mgm./kgm.) or ether.

BLOOD PRESSURE 1–4 DAYS AFTER NEPHRECTOMY

1	2	3	4
80	120	104	
94	144	90	
	92	130	
90	80	124	
118	80	106*	200
112	116	148	
96	100	136	
104–128	116–116	104	124
100–104	108	96*–126	108
96–100	112	148	
92	80	140*–138	
100– 90	128		
116	128		
110	92*	140	

* Peritoneal washing.

From the table it is evident (1) that the rise in blood pressure mostly occurs during the second or third day after nephrectomy; and (2) that peritoneal washing does not lower the pressure but may increase it. In some cases there were indications of an improvement in the state after washing, though the blood urea showed only a moderate fall.

The results indicate that since hypertension may occur in the absence of kidneys, some extra-renal factor is of importance for the development and maintenance of this type of state of hypertension in the rat. It is tentatively assumed that the normal kidney inactivates some extra-renal factor producing hypertension under certain conditions.

Influence of Choline and Ethanolamine on the Rate of Formation of Phospholipids in the Liver

THE work described below was carried out in the Biochemistry Department, University of Liverpool, but in consequence of war it had to be abandoned early in 1940. As the results have not been reported elsewhere, it was considered to be of interest to record them.

Using radioactive phosphorus, Chaikoff[1] made an extensive study of phospholipid metabolism, in which he showed that choline caused an increase in the rate of phospholipid turnover in the livers of rats maintained on a 40 per cent fat diet. The maximal increase of 30–40 per cent over the controls was reached six hours after the administration of choline by stomach tube. He suggested that the stimulation of phospholipid turnover was the mechanism by which the choline exerted its lipotropic action. McHenry and Patterson[2] have since supported this suggestion. It occurred to us, however, that this rise in the turnover rate might merely be a mass action effect due to the temporary increase in the concentration of choline, a constituent of the lecithin of the liver phospholipids. If this were the case, it would be expected that the increased rate of turnover would be confined to the lecithin fraction. It would also be expected that the administration, under similar conditions, of ethanolamine, which is not lipotropic[3,4], would also cause a rise in the rate of phospholipid turnover, the increase in this case being confined to the cephalin fraction. As will be seen, this was, in fact, found to occur.

As a preliminary experiment, the relative rates of lecithin and cephalin formation in fed and fasted rats were compared. Five rats on stock diet were injected with radiophosphate in saline, killed six hours later and the organs extracted with ethanol and ether after pooling and grinding with sand. The extracted lipoids were dissolved in ether and fractionated in the usual way. Five rats fasted 22 hours before death were treated similarly. The radioactivity of the samples was measured on a Geiger counter and the specific activity calculated. The specific activity is defined as the percentage of injected radiophosphate which is present per mgm. of phosphorus in the particular phosphatide preparation.

TABLE 1

	Specific activity of fed rats		Specific activity of fasted rats	
Tissue	Lecithin	Cephalin	Lecithin	Cephalin
Liver	0·42	0·29	0·31	0·21
Kidney	0·31	0·16	0·15	0·10
Small intestine	0·18	0·12	0·13	0·07

It can be seen that though the specific activity of the lecithin is greater than that of the cephalin, the relative increase from the fasted to the fed rats is approximately the same.

The influence of choline on the rates of turnover of the phosphatide fractions in the liver was determined as follows: ten rats were maintained on a 40 per cent fat, 10 per cent albumin diet, and on the seventh day each received an injection of radiophosphate in saline. Five rats received the diet as usual, while the other five had, in addition, 50 mgm.

TABLE 2

	Specific activity	
Group	Lecithin	Cephalin
Control	0·36	0·24
Choline	0·44	0·26

choline mixed with the diet. Six hours later the animals were killed, and the liver phosphatides extracted and fractionated.

It can be seen that the increase in the specific activity is confined to the lecithin fraction.

In order to compare the effect of ethanolamine feeding with choline feeding, 24 rats were given the high fat diet for six days and injected with radiophosphate on the seventh, as before, but 8 rats received 50 mgm. of choline by stomach tube and 8 rats received 50 mgm. of ethanolamine similarly. The total phosphatides were prepared from the livers and their activity measured.

This experiment was repeated, except that the ethanolamine dose was reduced to equimolar proportions to the choline, namely, 30–50 mgm., and the control group received 1 ml. of distilled water by stomach tube. The phosphatides were fractionated.

TABLE 3

Group		Specific activity		
		Total phosphatide	Lecithin	Cephalin
1.	Control	0·43		
	Choline	0·67		
	Ethanolamine	0·70		
2.	Control	0·39	0·44	0·35
	Choline	0·52	0·57	0·43
	Ethanolamine	0·69	0·57	0·77

It can be seen that the ethanolamine in both the experiments caused a rise in the specific activity, and therefore in the phospholipid turnover, similar to or greater than that produced by choline, the effect of each base being greatest in the phospholipid fraction of which it was a constituent.

As ethanolamine has no lipotropic action[3,4], it would seem unlikely that choline exerts its lipotropic activity by stimulating phospholipid turnover, unless lecithin plays a much more active part in fat metabolism than cephalin. In view of the similar rise in the specific activity of lecithin and cephalin from fasted to fed rats, this seems improbable. Chaikoff[1] found that methionine, which is lipotropic, caused a rise in the specific activity of liver phospholipids, but he also found that cystine and cysteine, which are negatively lipotropic, produced a similar rise. He suggested that this discrepancy was due to the short duration of the experiment. The same criticisms could be levelled against the results recorded here, but as the effect of choline on the rate of phospholipid turnover is itself lost after 12 hours, and the comparison of lipotropic and non-lipotropic factors was carried out under identical conditions, this seems scarcely justifiable. It would be desirable to extend this work with larger numbers of animals, but the results show that there is no correlation between the lipotropic activity of choline and ethanolamine, and their ability to stimulate phospholipid turnover in the liver.

We wish to thank Dr. J. H. Channon for his advice and encouragement, and Sir James Chadwick, from whom the radiophosphate was obtained, for his advice and assistance with the radioactivity measurements.

The Matter-Radiation Cycle in the Cosmos (and the Second 'Law'): the Sun's Equilibrium

IF one scrutinizes the chances of radiation, such as arises even in the observable part of the cosmos, escaping sufficiently to leave as low a temperature for interstellar matter as the 3·2° A. estimated (or even as the temperature of the earth)—on the supposition that nothing but heat (or re-radiation) is produced—one finds that it cannot possibly do so.

Knowing the fraction of a cross-section of the whole that is occupied by nebulæ (some 10^4 light years in virtual radius and 2×10^6 light years apart), and using the very low estimate of 20 per cent absorption in crossing a nebula (it is an average 60 per cent for the unusually large galaxy, at the sun's very eccentric location), it is found that the fraction of radiation penetrating to 5×10^8 light years, the limit of present well-defined observation, is about 0·997, and certainly cannot be as near unity as, say, 0·99999. But 0·997 corresponds to an interstellar temperature of $6{,}000 \times \sqrt[4]{1 - 0{\cdot}997}$, or about 1400° A., and even 0·99999 to 340° A. (Since photographs by the 100-inch reflector show objects that are likely to be nebulæ similarly distributed to a few times 5×10^8 light years, the case is actually stronger than this—observationally; hypothetically, it is stronger again, for one cannot easily think of space, whether infinite or in some way bounded, as unpopulated.)

Therefore, unless we wish to indulge in speculations about some entirely intangible third form of mass, we are forced to conclude that the trapped radiation is converted, mostly in the denser 'shells' of gravitationally and radiatively balanced matter between the stars, into more matter, such as returns to the stars in the manner known of as 'accretion'. Evidently a surface phenomenon, this is easily shown to occur at a rate far too small to be observed in the laboratory, namely, at some 4×10^{12} gm. per sec. in contact with, roughly, 10^{33} gm. After all, why should not a change that occurs at extremely high temperatures be capable of reversal at lower temperatures (one can add, speculatively, possibly at superconduction levels)?

It should be clearer than it is that the second 'law' of thermodynamics, of no account in the microcosmos, is only an appearance in the 'mesocosmos' (where we reside), which is counteracted in the macrocosmos of gravitational 'supremacy', a matter first evident in Jeans' 'gravitational instability'. Dean Inge had no need to write as virtually despairingly as he did in "God and the Astronomers".

A conclusion to be drawn from this is that an average star, such as the sun is providentially ('teleologically' is very like a synonym), tends to keep constant mass, although in the fashion, *cet. par.* (that is, apart from more 'teleology'), of unstable equilibrium; for accretion is proportional to $(\text{velocity})^{-3}$ and velocity is proportional to $(\text{mass})^{-1/2}$.

The subject will be discussed at more length in another place.

Crystal Structure of Cyanoethyl Cellulose

In the X-ray study of cyanoethyl cellulose filaments[1], made from products of varying cyanoethyl content, it has been found possible to identify at least two forms of crystalline structure. Fig. 1 is an X-ray diagram of filaments made from alkali-soluble material, containing in this case 2·0 per cent nitrogen, corresponding to a substitution of less than one group per glucose residue in the cellulose. The X-ray diagram can be seen to be somewhat similar to that of hydrate cellulose; the normal repeat of pattern of 10·3 A. (approximately) of the cellobiose residue is retained along the fibre axis. It is most probable that the substitution of the cellulose occurs throughout the whole structure, and in these circumstances the obvious falling off in definition of the X-ray diagram is due to distortion of the crystalline lattice, caused by the replacement of certain of the (OH) groups by (OC_2H_4CN) groups. Fig. 2 is an X-ray diagram of acetone-soluble cyanoethyl cellulose filaments containing on an average 2·73 groups per glucose residue; complete cyanoethylation can be represented by the formula: $(C_6H_7O_2.(O.C_2H_4CN)_3)_n$. A preliminary study of this fibre diagram has shown that the crystal structure is built up in the following way.

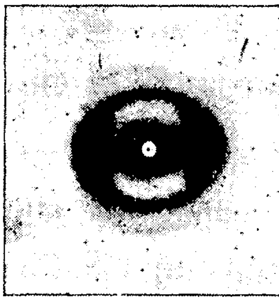

Fig. 1

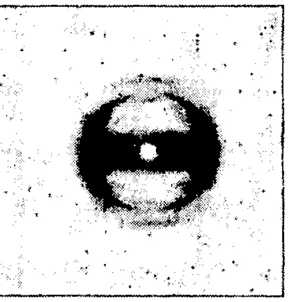

Fig. 2

Fig. 1. X-RAY PHOTOGRAPH OF FIBRES OF ALKALI-SOLUBLE CYANOETHYL CELLULOSE WITH A NITROGEN CONTENT OF 2 PER CENT. COPPER $K\alpha$ RADIATION. $D \approx 2{\cdot}1$ CM. (ON REPRODUCTION).

Fig. 2. X-RAY PHOTOGRAPH OF FIBRES OF CYANOETHYL CELLULOSE WITH AN AVERAGE SUBSTITUTION OF 2·73 CYANOETHYL GROUPS PER GLUCOSE RESIDUE. COPPER $K\alpha$ RADIATION. $D \approx 2{\cdot}1$ CM. (ON REPRODUCTION).

(1) The period along the fibre axis is $15{\cdot}2_1$ A., which indicates that the repeat is made up of three glucose residues. Hence the cellobiose configuration of the normal structure is not retained.

(2) The structure of the ether presents some difficulties in interpretation, as it is not fully substituted; but the X-ray diagram can be indexed at least to a first approximation on a hexagonal lattice, with the intense reflexions on the basal layer line arising from the (100) plane, and with the (010) and (020) reflexions absent or very weak. A structure may be assigned as follows: $a = c = 9{\cdot}7_4$ A.; $b = 15{\cdot}2_1$ A. (fibre axis); $\beta = 120°$.

This would be consistent with one chain per unit cell, containing three consecutive tricyanoethyl glucose residues arranged on a three-fold spiral along the fibre axis. Further, the above structure has a theoretical density of 1·28 gm./c.c., which is in good agreement with the value of 1·27 gm./c.c. found in white spirit. It is, however, emphasized that this postulated structure is only provisional and may well be a sub-multiple of a larger cell. At present, however, this has been found to be the best possible approximation.

Infra-red studies of the material have shown that in the cyanoethers of low substitution it is possible that some amide groups may be present. It also appears that some of the ethers of equal nitrogen content are soluble in water, whereas others are only soluble in alkali; the cause of this difference is most probably to be found in a more uniform substitution throughout the cellulose structure by cyanoethyl groups in the case of the water-soluble specimens. A final interpretation of the X-ray diagram of tri-cyanoethyl cellulose must await the elucidation of the problems of the types of ether groups present, together with data from a fully cyanoethylated specimen.

We wish to thank the directors of Messrs. Courtaulds, Ltd., for permission to publish this note.

X-Ray Diffraction Studies of a Nickel–Thoria–Kieselguhr Catalyst for Fischer–Tropsch Synthesis

A nickel–thoria–kieselguhr (100 : 18 : 100) catalyst prepared mainly according to Fischer and Meyer[1], and rendered completely alkali-free after reduction, by washing with water, was studied by the Debye–Shearer method.

A Debye – Shearer photograph of the kieselguhr used was taken before treatment. This photograph showed a number of sharp diffraction lines and a strong halo. It appears, therefore, that the kieselguhr consists of partly crystalline and partly vitreous or finely colloidal particles. The Bragg angles of reflexion and the spacings corresponding to the diffraction lines are given, along with their eye-estimated intensities, in Table 1.

TABLE 1

Bragg angles of reflexion for copper $K\alpha$ corresponding to diffraction lines	Spacings corresponding to diffraction lines	Eye-estimated intensity
10° 39′	4·20	m.s. (diffuse halo)
13 22	3·37	m.w.
14 48	3·02	m.
15 52	2·81	v.v.w.
17 55	2·54	v.w.
19 42	2·30	w.
21 30	2·11	w.
23 45	1·92	w.
24 21	1·87	w.
28 39	1·62	v.w.
30 20	1·52	v.w.

The X-ray diffraction diagram of a powdered sample of the nickel–thoria–kieselguhr catalyst shows the presence of a few diffraction lines of nickel together with some diffraction lines of the kieselguhr. The weak lines of the kieselguhr having Bragg angles 17° 55′ and 30° 20′ only appeared in this photograph. This shows that in the process of depositing nickel on the kieselguhr the structure of the latter has undergone a change. The two lines of the kieselguhr which appear in this photograph have been identified to be the strong lines of ferric oxide present in the kieselguhr. The lines of silica observed in the photograph of the kieselguhr are absent in that of the catalyst. It is therefore concluded that during deposition of metallic nickel and thoria on the kieselguhr the crystalline portion of silica (at least, a major part of it) becomes amorphous, while the structure and the crystallinity of ferric oxide present in the kieselguhr remain unchanged. The broadness of the lines, however, indicates that the crystal particles of ferric oxide have been disintegrated, yielding crystallites of smaller size.

At first it was thought that heating of kieselguhr in hydrogen during deposition of nickel and thoria was responsible for the change in its structure. To test this a powder photograph of the sample of kieselguhr previously heated at 450° C. in an atmosphere of hydrogen was taken. This photograph was exactly similar to that of kieselguhr taken before it was heated. This proves that heating alone is not responsible for the change of structure on deposition of the nickel–thoria. A photograph of kieselguhr on which only thoria was deposited according to the Fischer – Meyer method (*loc. cit.*) shows a pattern similar to that on which the nickel–thoria was deposited. The change in the kieselguhr, therefore, was brought about by the disintegration caused by the decomposition of the carbonates of nickel and thorium deposited as an initial step in the preparation of the catalyst.

The powder photograph of the sample of the nickel–thoria–kieselguhr catalyst after it has been used in catalysing higher hydrocarbon synthesis at 180° C. at atmospheric pressure is identical with the X-ray powder diagram of the same sample before use. The presence of nickel lines in the photographs proves that nickel is present in crystalline form in these samples. From the measurement of the glancing angles of reflexion of the nickel lines observed in these photographs, it appears that the lattice constant of nickel has not changed appreciably during its deposition on the kieselguhr. It may, therefore, be concluded that the atomic diameter of the nickel does not change during deposition or during the process of catalysing the Fischer – Tropsch synthesis under our experimental conditions.

The presence of two weak lines of thoria in the thoria–kieselguhr sample proves, on the other hand, the crystallinity of thoria deposited on the kieselguhr.

The X-ray data for the nickel–thoria–kieselguhr catalyst are given in Table 2.

The Measurable and the Non-measurable

IN the interesting address by Prof. H. Dingle, which appeared in *Nature* of July 26, 1947, there is one section about which considerable difference of opinion may exist. He quotes with disapproval the statement of Eddington ("Nature of the Physical World", p. 275), "The cleavage between the scientific and the extra-scientific domain of experience is not a cleavage between the concrete and the transcendental but between the metrical and the non-metrical", and he names the theory of evolution as completely confounding Eddington's assertion, because the theory of evolution is undeniably a scientific theory but it "has nothing whatever to do with measurement . . . it is concerned with qualitative changes alone . . . yet intelligent and learned men say and believe that science is concerned only with measurement !"

Surely it is not a quibble to deny that science is concerned only with measurement and yet to affirm that the domain of science is the measurable, that is, all the phenomena and experiences for which the fundamental units mass, length, time have relevance. The domain of ethics, æsthetics, the entire realm of values and significance is the non-measurable in the sense that the units $[M]$, $[L]$, $[T]$ are not applicable and have no relevance. The theory of evolution lies within the domain of science because it deals, though in a qualitative manner, with differences which are essentially measurable. There would be no theory of evolution if in the vegetable and animal kingdoms there were no observable differences in factors for which $[M]$, $[L]$, $[T]$ have relevance. An observer notes the difference between a ginkgo tree and an oak, between a crocodile, a horse and a man, without recourse to ruler and scales, but the differences are measurable and their existence has led to a theory which implies a time sequence. No one would suggest that if the time scale were accurately known, it would be entirely irrelevant to the theory of evolution.

The distinction between inquiries in the realm of the measurable and of the non-measurable has helped many people to place science in its right perspective relative to other approaches to knowledge and to truth. Such a generalization may be open to argument, but is it of so dangerous and vicious a nature that "the mask of comedy drops from it and it appears tragical" ?

The domain of the non-measurable is a matter of concern for everyone, and very particularly for the man of science who must step outside the domain of his own discipline to play an active part in this matter of ethics, because it is the misuse of science that confronts the present generation with a problem of first magnitude.

A. VIBERT DOUGLAS

Queen's University,
Kingston, Canada.

I CANNOT accept Dr. Douglas's view that because one could, but does not, measure the objects with which biology is concerned, one can therefore claim that the domain of biology is metrical. On those lines one could claim music and painting and poetry as sciences. However, our views do not matter, because Eddington himself has settled the question. He claimed to derive the ultimate laws of Nature from the *nature of measurement*, not from the character of the objects to which measurement was applied, and in his article on the cosmical number, reprinted in his posthumous work "Fundamental Theory", he proceeded to deduce them from the *details* of the act of measurement—the necessity for four entities such as the two ends of the measuring scale and those of the rod to be measured, etc. He sought to meet the difficulty of biology not by forcing it into the metrical scheme but by denying that it was science and classifying it with theology.

I agree that the distinction between the metrical and the non-metrical has led many people to place science in a perspective; I do not agree that it is the right perspective, and I still think that error on such a matter is tragical, whether it is an error that conforms to our prejudices or not.

A Rapid Method of Analysis for Certain Surface-Active Agents

WE note with interest a letter by S. R. Epton[1] which describes a partition end-point method for estimation of surface-active agents in solution. We can confirm that such a method gives accurate and reliable results, since a method similar in essentials has been in use in these laboratories for the last two years and was described by one of us in a lecture to students of the Manchester College of Technology in February of this year.

A complete description of our method, which embodies an improvement over the methylene blue method, was submitted for publication to a chemical journal on September 3, 1947.

"Structure of Spectral Lines"

IN *Nature* of August 23, p. 244, Dr. D. A. Jackson reviews my recent book on "High-Resolution Spectroscopy" (Methuen, 1947). After considerable hesitation and with much reluctance, I feel compelled to comment on several misrepresentations made by Dr. Jackson. That he appears to dislike my method of historical approach is a matter of personal taste with which I do not quarrel, but I cannot allow incorrect assessments of my views to pass unchallenged.

With regard to light sources, his failure to appreciate the wide range and applicability of the various hollow cathode sources I have described is fairly widespread, and indeed this common attitude was a prime reason for their inclusion. By far the biggest volume of published work in hyperfine structure has been made with the different varieties of hollow cathode source.

With regard to the atomic beam as a source, Dr. Jackson quotes me as saying (p. 82), "it is therefore very easy to miss weak components". My complete statement reads, "it is therefore very easy to miss weak components in a structure *if the beam is not dense enough*" (italics added). I think, too, in the circumstances, that the six lines of the review referring to the detection of weak components in potassium (made by Drs. Jackson and Kuhn) could well have been spared, since I give these very details on the following page, with due apportioning of credit.

What astonishes me is the accusation that I understate the superiority of the Fabry–Perot etalon, and I can only conclude that Dr. Jackson has not read my sentence on p. 89: "The Fabry–Perot interferometer has therefore greater power than any of the other instruments in general use". Needless to say, my treatment makes this so obvious that I am quite dumbfounded at Dr. Jackson's failure to appreciate my outlook. I devote 143 pages to instruments: 25 pages to the echelon, 38 pages to the Lummer plate and 80 pages to the Fabry–Perot etalon. If Dr. Jackson does not realize that fact, surely he saw the clear table on p. 88, where I place the Fabry–Perot at the head of the instruments listed in order of practical importance. I feel strongly that misrepresentation in this matter is highly undesirable in the interests of spectroscopy.

Dr. Jackson makes a good deal of play with the reflectivity measurements I have quoted (be it noted, from other workers). I heartily concur when he writes that but few and contradictory measurements are available, but he cannot have it both ways, for he then proceeds to remark: "If the curve had been drawn correctly . . ." May I ask on whose authority, and to which 'correct' curve does he refer? Is it perhaps to some unpublished figures of his own, since he is able to quote figures? Dr. Jackson prefers to select his mirrors with a photo-electric meter (which, incidentally, only measures the absorption, and not the reflectivity, an issue he side-steps), but I still prefer to use 'considered judgment' in my own experiments.

Again, with regard to reflectivity, Dr. Jackson states that sputtering is obsolete; but I have taken pains to show that some quite exceptionally good figures have been reported for sputtering methods, and this should be re-examined. However, I state explicitly on p. 113: "The superiority of the evaporated film over the sputtered film is evident". I personally also only use evaporation.

Finally, Dr. Jackson dislikes mountings of the reflexion echelon other than that he himself uses, and he argues that my discussion of the limitations of his mounting is irrelevant. Surely one might be a little less partisan, and in any case a text-book writer must be.

S. TOLANSKY

Royal Holloway College,
Englefield Green,
Surrey.

THE criticism which I made about Prof. Tolansky's description of the hollow cathode was that it is "concerned too much with complicated and obsolete forms". I do not fail to appreciate the work which has been done with this light-source in its most important forms, but I criticize the relative amount of space devoted by Prof. Tolansky to obsolete and little-used varieties.

With regard to the atomic beam in absorption, although it is established that this method permits the observation of lines too weak to be detected in emission, Prof. Tolansky does not mention this advantage, but deals at some length with the ease with which weak components are missed if the density of the beam is low. Obviously, weak components are not observed if the density of the beam is sufficiently low; but it is misleading to write that they are "missed", since if weak components were to be investigated a beam of low density would not be used.

Prof. Tolansky gives a curve for the reflecting power of silver layers, from which he derives values of the reflecting power of the silvered surfaces of an etalon which imply a resolving power too low by a factor of more than two; for this reason I wrote that the "general superiority and greater scope of the [Fabry–Perot] etalon is rather understated". The space devoted by Prof. Tolansky to the Lummer plate is approximately half of the total space given to the etalon and compound etalon. This attaches too much relative importance to the Lummer plate; the results obtained with this instrument compared with those obtained with the etalon are in a very much smaller proportion. The possibilities of the double etalon are understated by Prof. Tolansky. The value of this instrument depends to a great extent on the ratio of the interferometer gaps which can be used, and he states that a ratio of 4 : 1 cannot be exceeded (quoting Meissner, 1941). A ratio of 10 : 1 was used successfully in the examination of the resonance lines of lithium, in which intensity ratios of more than 10 : 1 are involved (Jackson and Kuhn, 1939); but Prof. Tolansky seems to have overlooked this.

With regard to the reflecting power of silvered surfaces, the contradictory measurements available to Prof. Tolansky were those of Strong, which give a reflecting power with red light of about 88 per cent when extrapolated for thick films, and those of Edwards and Petersen (*Phys. Rev.*, 50, 871; 1936), which gave a value of 98 per cent under similar conditions. Prof. Tolansky has drawn curves (Figs. 7.8 and 7.12) and derived all his conclusions with regard to resolving power of the etalon from the lower of these figures; if he had also considered the higher figure he would have obtained alternative much higher values for the resolving power, and would have seen that Meissner's estimate of the maximum ratio of the gaps in the double etalon, calculated on the basis of a reflecting power of 80 per cent, would be inappropriate. Direct measurements of resolving power have been made at Oxford (and are to be published); the resolving power found for red light with a film with a transmission of 4 per cent requires a reflecting power of 93 per cent, which implies a value of at least 97 per cent for a thick silver layer, in good agreement with the figure given by Edwards and Petersen.

The photo-electric meter measures the transmission of the silver layer for light of any required colour; the resolving powers corresponding to various values of transmission, extending over a large range, have been determined experimentally. The reflecting power can be calculated from the resolving power. Measurement of reflectivity is not therefore an issue which is side-stepped. Furthermore, when the photo-electric method is used, mirrors are not 'selected' after preparation; the density of the silver layer is controlled during the evaporation, and a layer with the requisite degree of transmission is obtained.

Prof. Tolansky appears to agree with my statement that evaporation has replaced sputtering (he "personally also uses only evaporation"); why then does he object to my criticizing him for devoting an approximately equal amount of space in his book to the two methods?

With regard to the mounting of the echelon grating, the aberration which Dr. Tolansky discusses cannot cause a loss of resolving power greater than 10 per cent except with objectives of shorter focal length than is permitted by the grain of the photographic plate; it was for this reason that I described a long discussion of this aberration as irrelevant. I might also have observed that another objection which Prof. Tolansky proposes (that the echelon might be curved and thus have focal properties) is not substantiated by experiment.

D. A. JACKSON

Control of Atomic Energy

THE article on the "Control of Atomic Energy" in *Nature* of November 15, p. 655, contains an important misstatement of fact that should not be allowed to pass without correction. It is stated: "The rejection by the Soviet Union of the very principles on which these proposals are based, including as they do the prohibition of atomic weapons, makes it difficult to see what further proposals can be advanced with any real hope of unanimous agreement".

This statement could only be taken to suggest that the Soviet Union has taken a stand against the prohibition of atomic weapons. In actual fact, the position is entirely different. Whatever may be the merits or demerits of the other parts of the Soviet plans on atomic energy control, the first point has always been the early conclusion of a convention to outlaw atomic weapons.

The first article of the proposed Convention, put forward by Mr. Gromyko as early as June 19, 1946, states: "The high contracting parties solemnly declare that they will forbid the production and use of a weapon based upon the use of atomic energy, and with this end in view, take upon themselves the following obligations: (*a*) not to use, in any circumstances, an atomic weapon; (*b*) to forbid the production and keeping of a weapon based upon the use of atomic energy; (*c*) to destroy within a period of three months from the entry into force of this agreement all stocks of atomic energy weapons whether in a finished or semi-finished condition".

The American and British Governments have so far not been willing to agree to such a convention until agreement on the wider aspects of control have been achieved.

E. H. S. BURHOP
(Hon. Secretary,
Atomic Sciences Committee).

Association of Scientific Workers,
15 Half Moon Street,
London, W.1.

WE regret to find that the article referred to contains an ambiguous statement. What we had in mind was that, according to information generally available, proposals for the control of atomic energy which included the prohibition of atomic weapons had been rejected as a whole by the representative of the U.S.S.R. We had no intention of suggesting that the Soviet Union was opposed to the prohibition of atomic weapons, and we do not think the phrase used need necessarily bear that construction.—EDITORS.

ORGANISATION OF THE CELL WALLS OF TRACHEIDS AND WOOD FIBRES

By A. B. WARDROP* and DR. R. D. PRESTON
Botany Department, The University, Leeds

DURING the past thirteen years the finer detail of structure in conifer tracheids has been the subject of some controversy[1,2,3,4]. This has centred round the fact that when transverse sections of conifer wood are examined between crossed Nicols three layers can be distinguished in the secondary wall of a tracheid, an outer and an inner layer which are bright, and a central layer, much thicker in late wood than the other two, which is dark. A similar behaviour is observed in cross-sections of wood fibres and is shown in the case of two isolated fibres of *Nothofagus cunninghami* in Fig. 1. On the basis of observations such as the run of striations in surface view, the orientation of crystals grown in the wall and the features associated with fungal attack, Bailey and his collaborators have claimed that the optical heterogeneity is due to different orientation of the cellulose 'micelles' in the three layers; in that while the micelles in the dark layer are orientated in a steep spiral, those in the outer and inner layers lie more or less transversely[1] or, in later papers, at angles between 45° and 90° to the length of the cell[3,5]. The case where the micelles in the outer layer are orientated transversely and those in the middle layer longitudinally is shown diagrammatically in Fig. 2 (*a*). On the other hand, Preston[2,4,6,7], criticizing the validity of the use of evidence obtained from swollen or otherwise distorted walls and basing his conclusions only on X-ray and optical examination of undistorted material, has maintained that the optical heterogeneity is to be explained largely by a pronounced difference in angular dispersion between the layers (Fig. 2*b*); and that, further, any wall layers with transverse orientation can only be present to an extent so small as to give no record on the X-ray diagrams of conifer wood[7] and to cause no disturbance in the optical properties of walls in surface view[7]. The apparently contradictory X-ray evidence brought forward by Bailey and Berkeley[3] was completely disposed of as an error in interpretation[6], and it seemed at that time that the case was at last clear so far as the physical evidence went.

There still remained, however, some unsatisfactory features. It had been shown by Wardrop[8] that if single walls of tracheids or wood fibres (which were shown by Bailey[1] to manifest similar optical heterogeneity) from abnormal wood with thick cell walls, for example, compression wood in conifers, was crushed and stained with Congo Red, at least two striation directions could be detected, the dichroic properties of which showed that they did, in fact, correspond to two different micellar directions. Since only a slight change in the major extinction position was observed during crushing, no major distortion of structure could have occurred. Although such observations were made on abnormal tissue, they did suggest strongly that the structure of normal tracheids needed re-examination. Further, though little emphasis can be laid on this, it appeared that the birefringence of the outer layer in tracheids was of the same order as that in fibres and this in turn was similar to that of the associated vessels where the micellar orientation is known to be almost transverse[8]. This observation clearly pointed to the danger involved in attempting to determine micellar inclination from the birefringence of a wall in transverse section in terms of the known characteristic birefringence of cellulose. It therefore became very desirable that a sufficiently critical experiment should be designed, to distinguish clearly and irrevocably between the two hypotheses, and it is with the results of what we regard as such an experiment that this communication is concerned.

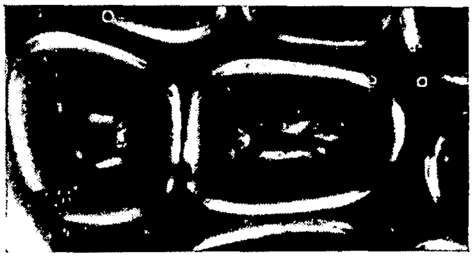

Fig. 1

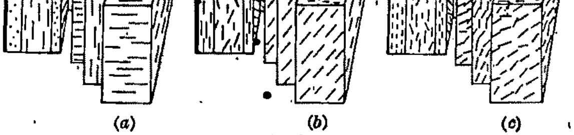
Since only one of the hypotheses demands any major net change in orientation between the wall layers, it had long been evident that if the birefringence of a transverse section of a cell could be studied as the section was tilted about a line perpendicular to the direction of observation and to one wall surface, a clear-cut distinction between the hypotheses could be made. Difficulties associated both with technique and the nature of the material made this impossible, but it occurred to one of us (A. B. W.) that the same observations could be made in another way. If a series of sections is cut from a piece of wood at increasing angles to the grain, then a series of observations can be made analogous to those which could have been made on a single, tilting cell. As the tilt of the section increases, the birefringence in one wall will increase, reaching a maximum where the section is parallel to the cellulose chains, and then decrease again. If, therefore, the whole wall is, in fact, uniform in micellar orientation, the birefringence of all layers should show a maximum at the same angle of sectioning; if, on the other hand, it consists of two or more coaxial spirals, then a maximum should be reached at different tilts for each wall layer. Among the disadvantages of this method as compared with the progressive tilting of a single cell it should be pointed out that, first, since different parts of different cells are being examined in different sections, an average birefringence for many cells has to be obtained; secondly, it is imperative that all the tracheids should have spirals of the same sign; and lastly, it is preferable that outer and inner layers should have



(*a*) (*b*) (*c*)
Fig. 2

---

* An officer of the Council for Scientific and Industrial Research, Melbourne, Australia.

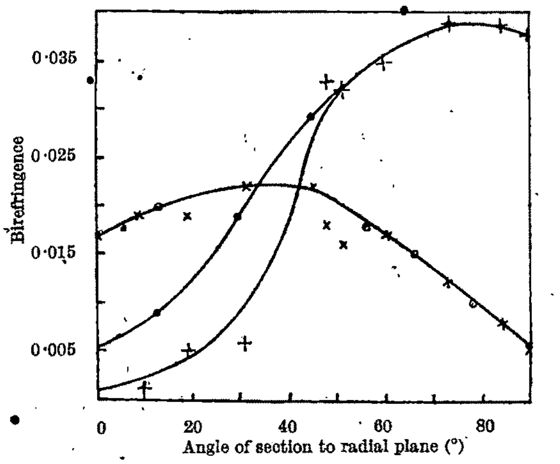


Fig. 3. *Picea*. Outer layer: ×——×, observed; ⊙——⊙, calculated. Middle layer: +——+, observed; ●——●, calculated

spirals of the same sign (even if the inclination of the spirals is indeed different). These conditions seemed to be met in a specimen of *Picea* sp. and in the fibres of *Nothofagus cunninghami*, and a series of observations was therefore made on sections from each. In both cases it was found preferable to deal with the tangential walls so that the sections were cut at increasing angles to the radial longitudinal plane. Phase difference determinations were made in sodium light with a de Sérnarmont compensator. The section thickness was later determined by turning cells on their sides and measuring directly with an eyepiece micrometer. The birefringence could then be calculated with accuracy. The orientation of the blocks of wood used to the tilting axis was kept constant so that, for example, the tangential wall nearer the pith in each cell of each section was always observed.

The results are shown graphically in Figs. 3 and 4, together with values calculated using the maximum birefringence determined experimentally. The first point to note is that the maxima do not correspond in inner and outer layers. In *Picea* the micelles in the outer layer are, on an average, oriented at an angle about 50° to the long axis of the cells, while in the inner layer the corresponding angle is 18°, comparing favourably with the angle 20° determined from the X-ray diagram. In *Nothofagus* it is somewhat difficult to determine the precise angle in the outer layer—it must lie somewhere between 90° and about 60° to the long axis of the fibres—but it is certainly much greater than the 10° (comparing with the 10° obtained from the X-ray diagram) of the inner layer. It seems, therefore, to be established by the only type of observation which could establish such a result, namely, by observation of the physical properties of untreated and undistorted walls, that the micelles in outer layers of tracheids and fibres, while not truly transverse, do at least form a spiral slower than that of the thicker layer within.

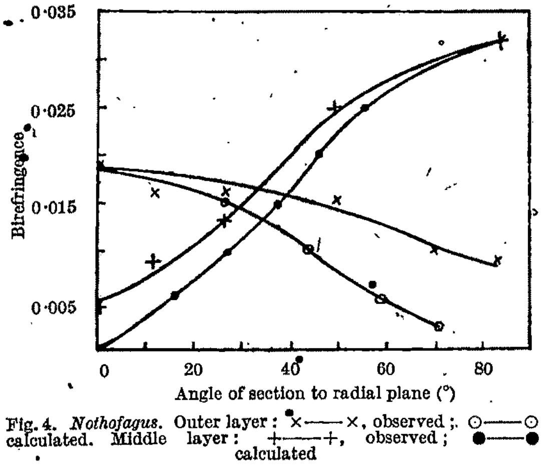

Fig. 4. *Nothofagus*. Outer layer: ×——×, observed; ⊙——⊙, calculated. Middle layer: +——+, observed; ●——●, calculated

On the other hand, however, it is equally clear that considerable angular-dispersion about this mean direction does also occur both in inner and outer layers, and that this also contributes materially to the optical heterogeneity. Thus in the inner layers, the intrinsic birefringence is obviously in the neighbourhood of 0·04, as compared with the 0·06 recorded for cellulose in ramie, cotton, etc. This lower value may be associated partly with the high lignin content of wood walls, but is certainly to be explained largely in terms of dispersion since we have observed a feature first reported by Preston[4], that the major extinction position of the wall as seen in section is often not parallel to the wall surface and is, in fact, sometimes perpendicular to it. Again, the low value of the birefringence (0·02) in the outer layer is probably due in part to the high lignification (much higher than in the middle layer, as shown by staining reactions similar to those used by Coppick and Fowler[9]) but probably reflects considerable angular dispersion. The inner layer is dark in transverse section, therefore, not only because the micellar spiral is a steep one but also because the considerable angular dispersion reduces the birefringence to a level materially lower than it would otherwise have been. Similarly, the bright outer layer is much less bright in transverse section than one would expect, again on account both of high lignification and angular dispersion. Until the determinations reported here were made it was therefore quite unsafe to attempt to make conclusions of any kind as to the interpretation of this particular kind of optical heterogeneity; and it is therefore satisfactory to find that, in fact, both the factors which had previously been stated to be causative are actually involved. The tracheids investigated here are, then, a modification of the type of organisation described by Bailey and Vestal[5], in which both inner and outer layers are spirally orientated, and is represented diagrammatically here in Fig. 2 (*c*).

One final point may perhaps be made. The low birefringence of the outer layers of the tracheids and fibres investigated here, reflecting as it probably does both a low cellulose content and a large angular dispersion, makes it seem rather unlikely to us that true striations should be visible in the outer cell wall layer. It would seem imperative that observation of striation direction should be checked against the optical and other properties of a wall before interpretation is attempted. It is satisfactory to note that the results of the investigation reported here have been used successfully by Wardrop and Dadswell[10] in an investigation of structure in tension wood fibres and compression wood tracheids.

A detailed account of the above investigations will be published later; for assistance with the sectioning we wish to express our indebtedness to the Forest Products Division of the Council for Scientific and Industrial Research, Melbourne, and to Mr. R. Metcalfe, of the Royal Botanic Gardens, Kew. We

debted to Dr. H. E. Dadswell, of the oducts Division, C.S.I.R., Melbourne, laboratory the exploratory observations , for helpful discussions of the problem.

ORPTION OF ULTRASONIC WAVES IN LIQUIDS

ELL-ATTENDED discussion on this topic s held by the Acoustics Group of the Physical on November 13 at the Imperial College. The was opened by the chairman, Mr. H. L. who said that experimental work in this field tstripped theory, and that he hoped experi- and theoretical workers would be brought r as a result of the discussion.

. M. M. Pinkerton (Cavendish Laboratory, Cam- outlined the differences between experiment e classical theories of Stokes[1] and Kirchhoff[2], oted by Biquard[3]. The calculations had d that the absorption would be caused by ty and heat conduction respectively; in liquids at conduction term is generally negligible in rison with the viscosity term. But the experi- l behaviour of gases is now accepted as due to axation phenomenon, in the interchange of y between internal and external degrees of m. The absorption α in the majority of liquids een shown to obey the relation $\alpha/\nu^2 =$ constant, ν is the frequency of measurement. This is ound for gases when ν is much lower than the tion frequency. To pursue the work to higher ncies and obtain highly accurate data a new d had seemed desirable; from war-time ence the pulse method had appeared to be the suitable. The first results using this method been published by Pellam and Galt in 1946[4]. Pinkerton's experiments had been made by the method independently[5]. Results were presented etail for water. α/ν^2 was found to be constant the range 7–70 Mc./s., within one or two per at constant temperature. There is a fall in of about nine times between freezing and boiling ts. The observed absorption follows the expected erature variation of Stokes' theory over the e 0°–95° C., although remaining always about e times too large. This is very remarkable.

he behaviour of other liquids, as judged from lished data[4–7], can be used to divide them into itrary classes: (1) liquids where $\alpha_{obs.}/\alpha_{calc.}$ is 1,500, with a relatively small positive temperature fficient of absorption; (2) those for which $\alpha_{obs.}/$ lc. lies between 3 and 10, also with a positive erature coefficient; (3) liquids with $\alpha_{obs.}/\alpha_{calc.}$ een about 1 and 3 and a relatively large negative mperature coefficient; (4) very viscous liquids ere the Stokes relation is obeyed. Liquids of sses (1) and (2) are non-associated organic liquids, d class (3) contains the primary alcohols and ater, all typically associated liquids. Values of $\alpha_{obs.}/\alpha_{calc.}$ show a nearly regular progression from amyl alcohol to water. Mercury is not anomalous[8], the theoretical absorption being shown up to 1,000 Mc./s. The consequences of a relaxation theory, as calculated by Kneser[9], Mandelstam and Leontovitsch[10] and others, are (*a*) a dispersion of the velocity, (*b*) a maximum in the value of $\mu = \alpha\lambda$; this would correspond to α/ν^2 falling from the constant value observed at lower frequencies. Neither consequence has been verified experimentally. Various ways of estimating the relaxation frequency expected put it in the region of 10^3 Mc./s. for benzene. Hence the lack of experimental proof of a relaxation effect might be accounted for, if the measurements had been made at too low frequencies.

The variation of absorption with concentration in mixtures shows the same distinction between associated and non-associated liquids in the few cases so far investigated. In the case of two pairs of associated liquids, there is an absorption maximum at an intermediate concentration. Four pairs of non-associated liquids show an initial rapid fall, followed by an asymptotic approach to the absorption value of the less absorbing liquid. This can be explained semi-quantitatively by introducing four relaxation times for the mixture and calculating, on certain extreme simplifying assumptions, the mean overall relaxation time as a function of the molecular concentration. The variation in relaxation time has then to account for the change in absorption. In no mixture investigated has a linear variation of absorption been found.

Dr. E. G. Richardson (King's College, Newcastle-on-Tyne) said he had carried out measurements between 100 kc./s. and 1 Mc./s. He outlined the sources of error in many of the experimental techniques used in the past, stressing the undesirable effects of excessive amplitude, and of the diffraction phenomena which occur. The use of very low powers is desirable, and the pulse method fulfils this requirement well. Measurements, using a hot-wire detector, of the diffraction pattern of a source at low frequencies have confirmed the absence of scattering, mentioned by Mr. Pinkerton. Measurements of the Doppler frequency shift of light scattered by various liquids had led Raman and Rao[11] to the conclusion that the velocity of 'hypersonic' waves (identifiable with Debye heat waves) is less than that measured at low frequencies. He was uncertain if it could be shown that all the ultrasonic energy absorbed appears as heat. A method of measuring absorption at low frequencies by propagating waves in a tube might be developed. Prof. L. Tisza had suggested that the observed behaviour of liquids could be represented by the introduction of a second coefficient of viscosity[12]. This point was taken up by Dr. Temperley later in the discussion. Another theory, in which the compressibility is relaxational, has been developed for water by L. Hall[13]. Dr. Richardson was concerned that any theory to explain the absorption behaviour of liquids should not introduce too many arbitrary constants, incapable of being verified independently.

Dr. H. N. V. Temperley (Cavendish Laboratory) discussed the possibility of a coefficient of expansion viscosity. Mathematically this is easily defined, and was introduced in his calculations by Stokes. This coefficient had been shown by Maxwell to be zero for gases, but seems to have been ignored for liquids. There are several theoretical models which might be used to calculate the absorption, based on the idea of a potential cell. Such models can in all cases lead to a finite expansion viscosity. A relaxation time can be involved in the readjustment of the molecules in potential cells to a small change in external conditions. He thought that any explanation of the behaviour of water must explain the variation of both the viscosity and the absorption with temperature, since these are so closely related. The distinctions drawn between associated and non-associated liquids make it clear that different theories must be developed for the two cases.

In the discussion contributions were made by Dr. P. Vigoureux, Mr. Bayard, Mr. D. O. Sproule, Dr. J. Lamb, Mr. Ribchester and Mr. E. Bauer. Dr. Lamb referred to the theoretical papers by Dutta[14], and Dutta and Ghosh[15] on dispersion and absorption of ultrasonic waves in liquids, and measurements by Rapuano[16] up to 250 Mc./s. Venkatswaran[17] had not confirmed Raman and Rao's results for dispersion of hypersonic waves.

FUTURE OF AGRICULTURE IN BRITAIN

IN a Friday evening discourse at the Royal Institution on October 31, Lord De La Warr discussed the prospects of British agriculture and how far it could help to meet the country's present problems of a shortage of dollars and the threat of an actual scarcity of food. The first essential, he said, is to decide the true nature of the trouble, whether it is a 'crisis' of temporary duration only or whether we are not rather being confronted with a fundamental change in our national economy. If the difficulties are merely short-term, it would seem that British agriculture has little contribution to make, since production has declined over the last two years both as regards acreage of tillage and livestock figures, and time will be needed to reverse this trend. Though increase of livestock may be the best way of farming to save dollars, the opportunity, which offered itself twelve months ago, of buying adequate feeding stuffs to do this had not been taken, so that the prospect of building up an animal population rapidly is not hopeful. During the last two years the whole world food situation has gone from bad to worse, and though this may be no one's fault, it must be admitted that interest in agricultural matters has been sadly lacking in the British nation as a whole. The word 'crisis' is, in fact, quite misleading, and its use has prevented us from realizing that the start we gained in the industrial revolution has r that cheap food and raw materials, wit sequent high standard of living to whi become accustomed, can no longer be granted. The idea that when the present ' we shall again be able to import all th require at a low price must be abandoned can hope to rebuild our shattered economy

During the last five years before the V Britain was importing on an average £50 annum more than it was exporting; that already begun to live beyond our means, then we have raised our standard of living. such as Canada, Australia and South An in the past were mainly food producers steadily industrializing themselves, therel their demands for British exports. Great in consequence, not likely to be in a fin economic position to pay for importing a proportion of food as formerly, and may e difficulty in exporting sufficient to pay for raw material to maintain her factories. It is able, moreover, whether the food is even a assuming we had the money to pay for it. the changes brought about by the industr of the great food-producing countries, there due to alterations in farming methods. The over from cereal growing to livestock pr that has occurred in the 'dust bowl' area United States and Canada means less grain a for human requirements. Furthermore, en increases in population are taking place in Inc Africa, as well as a rise in the consumption pe in these countries, due to the efforts to impr standards of health and nutrition among the peoples.

Other factors may prove of importance in ining future trends. The control of the tse and locust, for example, would open up new for agricultural development, which in the might temporarily offset this increased den food. On the other hand, the eliminatior mosquito would result in an even more rapi population in many areas.

For the purpose of feeding the people Britain, the products of British agricult therefore, literally of vital importance. The of £100 millions of food by 1952 demanded Government is moderate from the point of v the potentialities of the soil and the needs situation. In terms of the facilities now avail labour, houses, machinery, fertilizers and stuffs, however, the target is not likely to be r unless the drive behind it is intensified. It country, not the farming industry, that will su the necessary increased production is not atta and the facts and figures available point strong possibility of real hunger being expe during the next twelve months. However, the Britain is capable of producing more. Fou ago, 1½ million acres more were under cult than to-day, and there were more pigs and and about the same number of cattle.

More knowledge and better application of knowledge are needed. Means must be fou carrying over new information particularly to small farmer, and an improvement in the nat standard of education is probably the best sol to this problem. Compared with other countries farming efficiency in Britain is high; more is duced per head than in any other country in Eu

row 2½ times as much wheat per acre as in
d States or Canada. We are highly mech-
d in many cases our costs compare well
we have to import. Both soil and climate

future of Great Britain.

HOLOGY OF GLASSHOUSE CROPS

thirty-first annual report for 1945 of the
hunt Experimental and Research Station
s Hill, Cheshunt, Herts, 1946) sets forth the re-
several pieces of research into the pathology
house crops.

Mr. Williams has investigated the effect of tem-
re and humidity on the pathogenicity of
llium albo-atrum* and *V. dahliæ*. He finds that
lo-atrum* made very little progress when in-
ed to tomato plants growing in a closed
ber, with temperature and humidity higher than
al. The plants did not wilt in this environment.
dahliæ, on the other hand, caused about the
amount of disease in a closed chamber and
normal conditions. *Verticillium* wilts do not
to owe greater severity of attack to increasing
moisture. Cucumber plants wilted under con-
which checked the disease due to *V. albo-*
in tomatoes.

fungus *Didymella lycopersici* causes a severe
ot of tomato plants. Mrs. Enid Sheard has
that the disease can spread by air-borne
es, that an attack is more severe where plants
grown in soil which has been steam-sterilized
re inoculation than in unsterilized soil, and that
fungal strain which attacks only the fruit of out-
tomatoes will not cause stem rot under glass.
h O. B. Orchard, Mrs. Sheard has found that aerial infection is controlled by fumigation with formaldehyde vapour. W. H. Read has also attempted control of the disease by applying various fungicides to the surface soil of glasshouses, before and during planting.

I. W. Selman has found that fruiting tomato plants may show marked resistance to invasion by mosaic virus, and that inorganic nutrition also has an effect in promoting resistance to mosaic. Experiments are in hand to determine the nutrient balance most favourable to resistance. An interesting application for disease control by antibiotics is investigated by Erma Grossbard. A strain of *Aspergillus clavatus* has been used to depress the incidence of 'damping-off' of tomato seedlings by the fungus *Phytophthora cryptogea*. Antibiotic properties were also demonstrated against *Bacillus carotovorus*. Further trials with petroleum emulsion for the control of red spider mite have been made by E. R. Speyer and W. J. Parr. Large-scale use of D.D.T. has proved of value against the tomato moth, but applications of sodium ethyl xanthate against root-knot eelworm have not provided much hope of commercial control.

Several non-pathological investigations have also been made. They include the Station's continued work on general cultivation, an evaluation of the use of sulphur and sulphuric acid for making alkaline soils more acid, the choice of extractants in soil analysis, and the effect of plant hormones on the setting of tomato fruit.

FORTHCOMING EVENTS

Wednesday, December 31

Royal Microscopical Society, Section of Industrial Microscopy (in the Hastings Hall, B.M.A. House, Tavistock Square, London, W.C.1), at 5.30 p.m.—Mr. F. D. Armitage: "Microscopy of Paper".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Engineer in the Audio Frequency Section of the Research Department, based in London, Engineers (2) in the Field Strength Section of the Research Department, based at Oxford, Engineers (senior and junior) in the Designs Department in London—The Engineering Establishment Officer, B.B.C., Broadcasting House, London, W.1 (January 3).

Assistant Chemists (2) in the Chemistry Branch of the Department of Agriculture and Lands, Southern Rhodesia—The Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (January 5).

Superintendent in the Ship Division of the National Physical Laboratory in the Department of Scientific and Industrial Research—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2065 (January 7).

Rankin Lecturer (Grade I) in the Prehistoric Archæology of Western Europe, and a Charles W. Jones Lecturer (Grade II) in the Department of Ancient History and Classical Archæology—The Registrar, The University, Liverpool (January 8).

Lecturer in Electronics in the University of Adelaide—The Secretary, Universities Bureau of the British Empire, 8 Park Street, London, W.1 (January 12).

Principal Scientific Officer at the Royal Air Force Institute of Aviation Medicine, Farnborough, Hants, under the Air Ministry—The Secretary, Civil Service Commission, Scientific Branch, 27 Grosvenor Square, London, W.1, quoting No. 2071 (January 12).

Chief Conservation Officer in charge of the Conservation Branch of the Irrigation Department, Southern Rhodesia—Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (January 21).

Director of Museums—The Town Clerk, Municipal Buildings, Dale Street, Liverpool 2, endorsed 'Director of Museums' (January 26).

Chemist for an investigation of the isolation and analysis of the insecticidal constituents of pyrethrum flowers—Dr. S. H. Harper, Chemistry Department, King's College, Strand, London, W.C.2 (January 31).

Head of the Department of Physics (Senior Lecturer)—The Secretary, St. Mary's Hospital Medical School, Paddington, London, W.2 (January 31).

Director—The Director, National Museum of Wales, Cardiff (February 28).

Lecturer in the Department of Electrical Engineering and Physics—The Principal, Borough Polytechnic, Borough Road, London, S.E.1.

TECHNICIAN in the City Hospital Laboratory, Urquhart Road, Aberdeen—Dr. Smith, The Laboratory, City Hospital, Aberdeen.

DIRECTOR OF RESEARCH—The British Hydromechanics Research Association, 94–98 Petty France, London, S.W.1.

LABORATORY TECHNICIAN (male)—The Secretary, Department of Parasitology, School of Tropical Medicine, Pembroke Place, Liverpool 3.

HEAD OF THE SCIENTIFIC DIVISION—The Director of Research, British Boot, Shoe and Allied Trades Research Association, Satra House, Rockingham Road, Kettering, Northants.
